Malaspina Glacier is a large piedmont lobe on the coast of southcentral Alaska fed by glaciers from the St. Elias Mountains. It is known for its size and the immense folded moraines on its surfaces. The surface moraines move with the ice, forming patterns clearly recognizable in satellite imagery. From an exact repeat orbit, ERS-1 SAR images with a pixel spacing of \(12.5\) m were acquired on June 29, 1992 and June 14, 1993.\(^{(61)}\) The US Geological Survey (USGS) DEM of a 3 arcsec resolution of the same area was re-sampled to produce a DEM of \(30\) m spacing through an optimum interpolation method such as kriging.\(^{(62)}\) The resulting DEM was used for removing the geometric and radiometric distortions on each SAR image. Then the cross-correlation method was applied to the entire image area on the \(20 \times 20\) pixel grid to map surface displacement (Figure 6). The maximum velocity derived was \(399\) m yr\(^{-1}\). The velocity vectors close to the eastern edge of Malaspina Glacier are mostly in the range \(80–300\) m yr\(^{-1}\). Because terrain correction is performed and a long time interval of 1 year is involved, an accuracy of \(30\) m yr\(^{-1}\) is expected. A comparison with earlier measurements implies that the current results are consistent with those obtained using the more traditional
“point picking” method, indicating that this new approach is a practical and cost-effective way to measure glacier surface velocities.

Interferometry provides a methodology that greatly extends the accuracy of ice motion tracking. Massonnet and Feigl\(^{30}\) provided a special summary of the application of satellite radar interferometry (SRI) for tracking ice motion of glaciers and ice sheets. Interested readers can also refer to the article in this encyclopedia by Massonnet \textit{Elevation Modeling and Displacement Mapping using Radar Interferometry}.

### 4.5 Use of Backscatter to Map Lake Ice and Lake Depth

SAR backscatter images can also be used to study shallow tundra lakes.\(^{63}\) The North Slope of Alaska is a relatively flat and featureless region of tundra with thousands of lakes, located between the Brooks Range and the Arctic Ocean. Most of the lakes are shallow, with few exceeding 2–4 m deep, and apart from a short open-water season from June to August they are ice covered. During the summer the lakes provide important habitats for plants and animals. In winter those lakes that do not freeze completely to the bottom can continue to support aquatic life and serve as sources of fresh water, a material that is in short supply in an otherwise frozen landscape. Ice core analysis shows that ice on all lakes there includes a clear layer overlying a layer with tubular bubbles oriented parallel to the direction of ice growth. The clear ice may also be overlain by a discontinuous layer of bubbly snow ice. Sequential ERS-1 SAR images acquired in NW Alaska, winter 1991–92, show that backscatter from lakes is low (−16 to −22 dB) at the time of initial ice formation because the specular nature of the upper and lower ice surfaces cause the radar pulse to be reflected away from the radar. As the ice thickens during the autumn, backscatter rises rapidly. The radar backscatter of floating ice can quickly reach the maximum values of the order of −6 to −7 dB. Once the ice freezes to the lake bottom, low backscatter values of −17 to −18 dB are observed. Model analysis\(^{63}\) indicates that the strong forward scattering caused by tubular bubbles and the reflection at the ice–water interface jointly result in a double-bounce mechanism, which is responsible for bright appearance of floating lake ice on radar images. Using a sequential SAR images to track when and where the lake ice becomes grounded, Kozlenko and Jeffries\(^{64}\) were able to depict the bathymetry of the tundra lakes. The results are of vital importance to studies of tundra lake ecosystems and monitoring of the impact of climate changes in the region.

### 4.6 Use of Visible Images and Synthetic Aperture Radar Interferometry to Map River Ice

Aufeis deposits (also called overflow ice, stream icings or naleds) develop on many rivers in high latitudes and in alpine regions. They form when the water pressure in streams is great enough to force water through cracks in the ice cover. The resulting overflows refreeze into additional layers of ice on the surface. The increased hydrostatic pressure generally results from restricted water flow caused by ice growth in stream channels. Refreezing of the overflowing water occurs during periods of subfreezing air temperature; such conditions almost always exist in polar regions during winter. Calcium carbonate deposits on some icings indicate that sometimes water has flowed through calcareous bedrock.\(^{65}\) Climate, hydrology, geology, permafrost and topography influence the occurrence of aufeis and fluctuations in its activity.\(^{66}\) Deposits of aufeis form every year on many rivers on the North Slope of Alaska, and, through repeated episodes of overflow and freezing, they may reach thicknesses of more than 3 m. The presence of aufeis in a drainage basin tends to stabilize river discharge in the same way as a glacier does, by providing melt water during hot, dry periods. For example, the Sagavanirktok River has no glaciers in its drainage area, yet its flow remains strong all summer,
partly due to the melting of aufeis deposits which range in area between $10^2$ and $10^3$ km$^2$. Indeed, the melting aufeis contributes to the difference in hydrographs between the Sagavanirktok River, which has extensive aufeis deposits in its headwater area, and the Kuparuk River, which does not; both rivers enter the Arctic Ocean within 20 miles of each other near Prudhoe Bay. In addition, areas susceptible to icing may present engineering problems for construction of buildings, highways and other structures. Therefore, it is important to know the distribution and volume of aufeis in a drainage basin.

It is possible to map aufeis using Landsat Multispectral Scanner (MSS) imagery. The visible wavelength (MSS band 5) data can be used to map residual ice after the spring thaw and the NIR wavelength range (MSS band 7) is useful for mapping late-winter and spring overflows. In an extensive investigation of Alaskan aufeis deposits, using Landsat imagery, Dean found that most icings on the North Slope occur east of the Sagavanirktok River, where many icings coincide with known springs. Landsat imagery has proved useful in locating aufeis deposits at the end of winter but, because of the lack of solar illumination, aufeis processes cannot be mapped with visible and NIR imagery during the winter when the accumulation is most active. On the other hand, after the aufeis deposits have formed in the fall and continue to grow during the winter, the surface changes are subtle. This makes the use of remote sensing for investigating winter aufeis processes even more difficult.

Li et al. have used interferometric coherence to map aufeis. The interferometric coherence between two radar acquisitions was used to map the distribution and development of aufeis in the study area. Coherence is a measure of the degree of resemblance of radar phases between two SAR images acquired a few days apart. If accretion occurs in the time between passes, the coherence between phases from two acquisitions over the aufeis is low relative to the surroundings. A time series of 12 interferograms were produced to cover the time period between January and March 1994. Both are important tributaries of the Sagavanirktok River.

A time series of 12 interferograms were produced to cover the time period between January and March 1994. Both are important tributaries of the Sagavanirktok River.

On all interferograms, lakes and aufeis deposits along the rivers all show significant irregular changes in radar returns, as indicated by low coherence values. In the northern part of the coherence map (Figure 7), many lakes, ranging in size from a few hundred meters to 1.5 km, all appear dark. To the south of the junction of the Ivishak and the Echooka rivers, a narrow band along the Ivishak River is identified as an area of active aufeis development based on its proximity to the river channels and its dark appearance on the coherence map. Similar patterns are also seen on all other interferograms in the time series.

Since the time series of interferograms started in January, the lakes were clearly frozen at that time. It is also certain that these lakes were not affected by overflows. The low coherence value of the lakes is caused by the lowering of the ice–water interface as the ice thickens. This boundary is the major scattering interface, so lowering it changes the scattering characteristics with respect to radar propagation. This increases the randomness in the phase relations between the two passes and leads to a low coherence value. For the aufeis areas, the accretion of new ice layers on top of the ice cover changes both the surface and the internal scattering pattern in a random manner, resulting in irregular changes of the phases over the extent of aufeis deposits. Consequently, the coherence between phases from the two passes over the aufeis is significantly lower than for all the other objects. Although both lakes and aufeis deposits appear dark in the coherence map, it is possible to distinguish one from the other, because (1) the locations of the lakes are known, (2) aufeis deposits always occur along river channels and (3) the backscatter
values of active aufeis always change, whereas the most significant lake ice backscatter changes occur primarily when the lake ice freezes to the bottom.\(^\text{63}\) Owing to a lack of significant backscatter changes, most lakes disappear in the background, leaving aufeis as the only prominent object in the backscatter change maps, which are one of the by-products of SAR interferometric processing.

### 5 REMOTE SENSING OF SOIL MOISTURE

#### 5.1 Use of Microwave Brightness Temperature for Soil Moisture

The microwave emission from soil is strongly dependent on the near-surface soil moisture content. Water has a dielectric constant of about 80 at the L-band compared with 3.5 for dry soil, and it may occupy 0–59% of the total soil volume, depending on external conditions and soil type. Consequently, the effective bare-soil emissivity may range about 0.6 for wet soil to 0.9 for dry soil. Competing effects from variations in soil temperature, surface roughness, vegetation cover and soil texture reduce the overall sensitivity of microwave brightness temperature (radiobrightness) to soil moisture. Moisture remains a dominant effect, however, as long as the vegetation cover is moderate.

The application of microwave brightness temperature in other regions provides useful information to researchers on polar regions. Using data sets acquired by an airborne electronically scanned thinned array radiometer (ESTAR) at Washita watershed in southwest Oklahoma in June 1992, Jackson et al.\(^\text{74}\) derived soil moisture over a large area. The watershed was saturated with a great deal of standing water at the outset of the study. During the experiment of nine contiguous days there was no rainfall and the surface soil moisture exhibited a dry-down pattern over the period. Significant variations in the level and rate of change in surface soil moisture were noted over areas dominated by different soil textures. ESTAR images acquired on eight days over the nine-day experiment period show spatial patterns that are clearly associated with soil textures and temporal patterns of drainage and evaporation processes. Because ESTAR is a synthetic aperture passive microwave radiometer and it was flown at an altitude of 2200 m or lower, the resulting data sets have a grid size of 200 m and a swath of 3.2 km. The images were formed into a mosaic to cover larger areas, and the finer grid cells of the original images were integrated into larger cells of 9 × 9 km, which is close to what satellite passive microwave radiometers can achieve. The results show that a strong relation is retained between the passive microwave brightness temperature and spatially averaged soil moisture.

While the soil moisture in the top 2–5 cm layer can be directly estimated through a single snapshot by a passive microwave radiometer, Galantowics et al.\(^\text{75}\) have demonstrated theoretically that sequential data assimilation through Kalman filter optimal estimation can retrieve the profile of soil moisture and temperature from periodic passive microwave observations. In their analysis, a 1-m soil state profile was recovered over an eight-day period from daily L-band observations following an intentionally poor initial state estimate.

In addition, multiple frequency passive microwave measurements in the 6–18 GHz range have been used to retrieve multiple parameters of land surface, including soil moisture, vegetation water content and surface roughness.\(^\text{76}\) This approach has been tested using data from the Nimbus-7 SMMR for the years 1982–85 over African Sahel. The approach discriminates well between soil moisture, vegetation and temperature variations.

#### 5.2 Use of Single Band Synthetic Aperture Radar Backscatter

SAR backscatter is used to estimate soil moisture. Because the radar return is strongly related to soil moisture content,\(^\text{77–79}\) ERS-1 SAR can be used to map soil moisture conditions. Li et al.\(^\text{80}\) generated a SAR mosaic for the entire state of Alaska using ERS-1 SAR images. The mosaic is particularly useful for this application. On the mosaic, three gigantic bands with each having backscatter values distinctively different from those in the other bands are seen between the Brooks Range and the Arctic coast (Figure 8).

The first band of high backscatter values along the Arctic coast stretches about 500 km between the delta of the Canning River in the east and the Icy Cape in the west. This band has a width ranging from 50 to more than 5.1 Use of Microwave Brightness Temperature for Soil Moisture

100 km and is characterized by numerous arctic lakes and flat terrain. Geographically, the band coincides with the Arctic coastal plain. The existence of numerous lakes exerts a strong influence on the high backscatter level of the band. On the mosaic, most lakes look very bright. This agrees with other investigators’ observations\(^{81}\) that arctic lakes usually have high backscatter during short summer. The high radar backscatter from lakes in summer is caused by roughening of the lake surface due to strong winds. In fact, weather records have documented that surface wind speeds along the Arctic coast are persistent and strong compared with those in more interior regions. It is of particular interest that the areas between the lakes also contribute significantly to the high backscatter values of this band. For example, near the Oliktok Point, to the west of the Sagavanirktok River, the coastal plain appears bright in the mosaic. Close examination indicates that land between lakes has a higher backscatter value than lakes in the area and the overall high backscatter level in the vicinity is mainly caused by backscatter from land. A previous geological survey of the area\(^{82}\) reported that the ground cover of this area is wet tundra where the peaty soil has a shallow, active layer and is saturated throughout the summer.

To the south of the first band lies the second band of distinct radar backscatter values. This band of relatively low backscatter values is about 50 km wide on average. This band is the Arctic foothills characterized by rolling uplands of moist tundra.

Further south is the third band of the Brooks Range, with distinct mountainous radar backscatter characteristics, i.e. very bright foreslopes and dark backslopes.

The bright appearance of wet tundra and the relatively dark signature of moist tundra agree with the model and laboratory experimental results regarding the proportional relation between soil moisture and radar backscatter values for bare soils.\(^{77}\) The low biomass in tundra makes the application of the bare soil moisture model relatively straightforward.

### 5.3 Use of Dual-polarization Imaging Radars

In the previous section, it was discussed that radar backscatter increases with increase in soil moisture. However, soil surface roughness also plays an important role in determining radar backscatter. For such a problem with more than one unknown, multiple polarized backscatter would provide a better solution. In practice, dual copolarized backscatter (HH and VV), instead of full polarimetric SAR, is used for the estimation of soil moisture. Backscatter obtained by imaging radars with longer wavelength, such as the L-band, is particularly useful in this application because of the deeper penetration into the soil. Omitting the usually weaker cross-polarized (HV or VH polarization) returns makes the estimation less sensitive to system noise and the presence of vegetation, and simplifies the calibration process. Empirical algorithms have been developed for inverting soil moisture content and surface root mean square (RMS) height from imaging radar images. Based on scatterometer data, Dubois et al.\(^{83}\) derived empirical equations for L-band dual copolarized backscatters as functions of two unknowns: RMS and dielectric constant. Because the two unknowns can be solved from measurements of copolarized backscatters from two independent equations, and the dielectric constant of soil can lead to soil moisture, estimation of soil moisture is feasible. The algorithm is tested with data sets acquired with the AIRSAR system and used to derived soil moisture images using space-borne SIR-C SAR data. A comparison with in situ data acquired at Chickasha, OK, shows that the algorithm infers soil moisture with an accuracy of 4.2%. The best results are achieved when the surface roughness is around 10 cm RMS for the L-band, the incidence angle is >30° and the volumetric soil moisture content is <35%. Shi et al.\(^{84}\) developed an algorithm based on a fit of a more theoretical model, the single scattering integral equation method. The algorithm is applied to basically the same L-band copolarized SAR image data. The RMS error of soil moisture was found to be 3.4%.

### 6 REMOTE SENSING OF ARCTIC VEGETATION AND FOREST FIRE

The world’s boreal forest region is an active component of the Arctic and sub-Arctic regions. The total boreal forest covers a little less than 10% of the total land surface. Recent surveys indicate that 714 Gt of carbon are stored in the vegetation and ground layers of the ecosystem found in the boreal forest region, which represents >37% of the total terrestrial carbon pool. Boreal forest can be divided into two basic classes: those dominated by black spruce and those dominated by white spruce, based on their relation with microclimate and climate change. In Alaska, the white spruce forests are typically found on sites with warmer and better drained soil conditions, while black spruce forests are found on sites with cooler and more poorly drained soils. These local conditions are the primary factors behind the patterns of above- and below-ground carbon accumulation. In mature white spruce forests, the carbon levels are 70–90 t ha\(^{-1}\) in the living and dead vegetation and 20–40 t ha\(^{-1}\) in the ground layer. The cooler growing conditions in mature black spruce forest leads to lower carbon accumulation in the vegetation layer (20–30 t ha\(^{-1}\)), but higher levels of carbon in the ground layer because of lower rates of decomposition.
Thus, on average, there is more carbon stored in black spruce than in white spruce forest. In a global warming scenario, a shift from black spruce to white spruce is to be expected.

It is well known that the boreal forest in the Upper Yukon and Koyukuk regions is especially prone to destruction by fire. Many trees have branches to the ground and commonly are covered with lichens and mosses. Shrub undergrowth abounds. Relatively low precipitation, long hours of sunshine and very high air temperatures accompanied by low relative humidity in summer greatly increase the fire hazard in an already flammable region where mosses and lichens are extremely dry. Once caused by either lightning or human accident, fire spreads readily in such an environment. Because the forest fires in the region are widespread over large inaccessible areas, it is essential to map the extent of forest fires, especially the extent of the most recent ones, using satellite imagery. Recent studies have shown that old fire boundaries (up to 40–50 years old) can be mapped in the boreal forest zone using Landsat TM data. This is possible because of the sensitivity of the shortwave IR bands of TM to patterns of regrowth in these forest. SAR imagery is also a useful tool for the identification of forest fire scars in the Arctic region. On the Alaska SAR mosaic, several conspicuous bright patches have been found in the Upper Yukon and Koyukuk regions (Figure 9). These patches range from 10,000 to 500,000 acres in size. A comparison of the mosaic with the forest fire records collected at the US Bureau of Land Management shows that all those bright patches are recent forest fire scars. Table 1 lists the five largest bright patches in the region. Of these five patches, four are scars of 1991 forest fires and the remaining one is a 1990 fire scar. Also, the sizes of the fire scars estimated from the SAR mosaic compare with the fire records fairly well. Considering that the component SAR images were acquired in 1992, the ability of the mosaic to map the recent boreal forest fire scars is very encouraging.

According to Kasischke et al. and French et al., recent boreal forest fire scars can be identified on ERS-1 SAR images based on the difference in their radar backscatter from the surrounding areas. The difference in image intensities between burned and unburned areas is mainly caused by exposure of soil in the burned areas. Many boreal forest scars have brighter SAR signatures because severe forest fires burn the forest canopy completely and expose bare soil to radar illumination. Furthermore, severe fires consume the surface peat layer which insulates the ground and helps lower the average ground temperature. Elimination of this insulating layer causes a 5–7 °C increase in average ground temperature for at least several years after the fire, which in turn causes a melting of the underlying permafrost and an increase in soil moisture. As mentioned in section 5, a higher moisture content in bare soil leads to stronger radar

backscatter in general. This explains why many recent forest scars appear brighter on SAR images. On the other hand, the burned areas may have low soil moisture due to better drainage, resulting in lower SAR backscatter values. Also, regrowth of vegetation on fire-disturbed areas can either increase or decrease the image intensities by masking the effect of soil moisture on radar backscatter.

It is interesting that variation of SAR backscatter within individual patches may even give a clue to local forest fire history or the variation in damage caused by the fire. For example, the patch Coleen_2 between Graphite Lake and the Coleen Mountain, centered at 67°08'N and 143°15'W, has an assorted dark and bright appearance in image intensities. Further examination of the fire records shows that the dark middle part of the patch also experienced an earlier fire between June 28 and October 1, 1988. To the north and south of this part, the areas with only the damage of recent fire (1991) show a much brighter radar signature. Another example is the patch Coleen_1 between Rabbit Mountain and Spike Mountain, with its central location at 67°30'N and 142°W. This patch experienced fire between June 24 and September 14, 1990. Detailed fire records show that this fire scar is actually related to five smaller fires in the vicinity. In other words, this area was not uniformly burned. This explains the variation of SAR signatures within this large patch.

Earth-observing satellites primarily gather information about the environment as digital images acquired by multispectral imaging sensors. These images consist of large arrays of picture elements (pixels). Images are usually recorded in 3–7 spectral bands, though new generation sensors providing 18–36 spectral bands are in development. The spectral bands are located in the visible, infrared, millimeter, and microwave parts of the electromagnetic spectrum. The spatial resolutions of images at the subsatellite point at ground level (dictated by the sensor’s instantaneous field of view, IFOV) are principally in the range 10 m–1 km depending on the satellite. Very-high-resolution satellite-borne sensors providing imagery with resolution as high as 1 m will soon become routinely available. Images are primarily used for mapping Earth resources and monitoring the state of the environment (terrestrial, atmospheric, and oceanic). Pixels consist of digitized radiances which are usually quantized on a scale of 0–255. Interpretation of surface features requires the images to be processed and classified by computer. The processing involves several stages, typically: (1) geometrical rectification and adjustment to a suitable cartographic coordinate system, (2) correction and calibration for atmospheric or system effects on detected radiances, (3) classification or product generation. Classification involves the transformation of the detected multispectral radiances in the image into meaningful descriptors of the surface – usually as thematic classes which can be displayed as a map. The mathematical conversion process is usually based on training an appropriate classifier algorithm by use of example spectral radiances from known surface objects (ground truth data).
Classifier algorithms may either be nonparametric or parametric (e.g. based on a statistical model). Neural network algorithms have found useful application as classifiers for satellite image data. Products may also be generated by computing environmentally meaningful indices from spectral radiances such as the normalized difference vegetation index (NDVI).

1 INTRODUCTION

1.1 Remote Sensing, Major Applications, and Need for Image Processing

The science of satellite remote sensing, also frequently known as Earth observation, began in 1960 with the launch of the first civilian (nonmilitary) satellites designed for meteorological observation. The TIROS series (Television and Infrared Observation Satellite) became the first satellites to acquire images of synoptic weather patterns and in so doing provided an expedient tool in meteorological forecasting and climate modeling. This remained the principal application of remote sensing until 1972 when the first satellite was launched dedicated to the monitoring of the Earth’s land surface using a multispectral imaging system. This satellite was known as the Earth Resources Technology Satellite (ERTS)-1 but was later renamed Landsat-1. The Landsat series has since proved to be one of the main sources of global environmental information ever conceived and still continues to provide valuable data with the satellites making a repeat coverage of the entire planet every 16–18 days. Program continuity over several decades has been of inestimable value in monitoring gradual or long-term changes in the biosphere and natural ecosystems (such as progressive soil degradation, desertification, deforestation, increasing urbanization, and loss of biodiversity).

The main advantage of satellite remote sensing over alternative forms of environmental data gathering is that large global surface areas can be monitored without the need for labour-intensive ground level surveys. In addition, satellite observations are also less costly than aerial surveys per unit of Earth surface area in the context of long-term/large-area mapping and monitoring. It is estimated that by the year 2000 the total volume of data gathered by Earth observing satellites will be of the order of 10 Tbytes per week, mostly consisting of digital images. These will be derived from a variety of sensors operating in different parts of the electromagnetic spectrum on-board a collection of satellites built and launched by many different countries, governmental agencies, and commercial enterprises. One of the main reasons for the expansion of data gathering capability has been the growing concern over environmental changes. In the United States this resulted in the development of the Earth Observing System (EOS) which is the cornerstone of the Earth Science Enterprise (ESE) program of the National Aeronautics and Space Administration (NASA). The EOS encompasses a number of satellites each housing several different sensing systems each aimed at assessing specific hydrologic, biogeochemical, atmospheric, ecological, and geophysical processes.

Images from remote sensing satellites need to be processed by computer in order to gain maximum utility from them. Images record the radiance, reflectance, or backscatter of electromagnetic radiation from terrestrial surfaces. Image processing is thus principally concerned with the identification of particular terrestrial features or measurement of environmental variables through analysis of the spectral observations encoded in the digital multispectral images recorded by the satellite sensor.

1.2 Spectral Characteristics of Natural Surfaces

The reflective or emissive properties of terrestrial surfaces differ significantly. This provides the key to satellite observation of the Earth. Figure 1 shows typical reflectance spectra of common terrestrial surfaces through the visible and near-infrared part of the spectrum. Such reflectance curves should be taken as being indicative only, since precise spectra of particular surfaces observed may vary significantly depending on the condition or composition. Water has a very low reflectance throughout the visible and infrared region. Wet soils therefore generally have lower reflectance than dry soils. Vegetation has high reflectance in the 800–1200 nm near-infrared region. The reflectance of diseased or damaged vegetation is usually reduced markedly in this region. The spectral bands of satellite sensors are strategically located at the sensor design stage to facilitate easy identification of surface types by analysis of the signature detected across all the bands. The bands must also be located at wavelengths at which the Earth’s atmosphere is highly transparent. The atmosphere is relatively highly transparent at visible wavelengths, though absorption bands of water vapor, carbon dioxide, oxygen, ozone, and trace gases become significant in the infrared region. The presence of dust and aerosols can affect the transmission of electromagnetic radiation throughout the visible region.

2 RECENT SATELLITES

2.1 Optical/Infrared Systems

Table 1 lists the principal remote sensing satellites which have been operational during the 1990s and also includes those which are due to be launched in the late 1990s for
The main satellites providing multispectral optical and infrared imagery can be divided into three groups:

- those providing relatively low-to-medium spatial resolution imagery (primarily for meteorological applications or global environmental change monitoring, such as the National Oceanic and Atmospheric Administration (NOAA) series, and the more recent ENVISAT and TERRA satellites, all giving imagery with spatial resolutions in the 250 m–1.1 km range);
- those providing high spatial resolution imagery (primarily for mapping and monitoring applications, such as the Systeme Probatoire de l’observation de la Terre (SPOT) and Landsat series with spatial resolutions in the 10–30 m range);
- those providing very high spatial resolution (primarily for detailed mapping applications, such as the later additions to the Indian remote sensing satellite (IRS) series and new generation satellites such as QuickBird with spatial resolutions in the 1–5 m range).

In addition, the SPOT-4 satellite is notable in combining sensors with high and low spatial resolution. The more advanced low-to-medium resolution sensors such as the medium resolution imaging spectrometer (MERIS) on the ENVISAT satellite and the moderate resolution imaging spectrometer (MODIS) on the TERRA satellite have much higher numbers of spectral bands in comparison to earlier sensors.

In the optical and infrared region of the spectrum, all of the satellites mentioned above rely on the use of passive radiometers which measure either reflected solar radiation or blackbody emission from terrestrial surfaces. Currently, however, “active” laser-based systems are also under development for measurement of vegetation canopy height. The first remote sensing satellite carrying an operational sensor of this kind will be the Vegetation Canopy Lidar (VCL) mission which forms part of NASA’s Earth System Science Pathfinder Project (ESSP).

### 2.2 Radar Satellites

Table 1 also lists the principal remote sensing satellites which provide radar imagery in the C and L bands. These include ERS-1, ERS-2, JERS-1, Radarsat and ENVISAT. These all provide high-resolution ground images at microwave (centimeter) wavelengths by using the signal integration technique of “aperture synthesis”. This technique enables the sensor to generate very-high-resolution radar images by effectively simulating the existence of a very large baseline antenna on the satellite.

* In most cases only the main imaging sensor is indicated although some of these satellites carry multiple sensing systems. This table is not exhaustive. HRV, high resolution visible; HRVIR, high resolution visible and infrared; TM, thematic mapper; AVHRR, advanced very high resolution radiometer; LISS, linear imaging self-scanning sensor; QBM, QuickBird Multispectral; QBP, QuickBird Panchromatic; ETM+, enhanced thematic mapper+.

The synthetic aperture radar (SAR) images so obtained are extremely valuable as an adjunct to HRV or infrared imagery obtained from other satellites. A comprehensive treatise on the SAR technique is provided by Curlander and McDonough. The advanced SAR (ASAR) system under development for the ENVISAT satellite provides radar images with multiple polarizations.

3 IMAGE CAPTURE SYSTEMS AND TRENDS

3.1 Imaging Geometries

Remote sensing satellites use a combination of their orbital motion and a mechanical or electronic system to build up images covering the ground beneath the satellite as it moves in orbit. Some satellites also have the capability to view locations off-nadir (and can be programmed to do so according to “customer” requirements). The most common type of imaging geometry now used is the “push broom” geometry (Figure 2) in which the satellite captures complete lines of pixels simultaneously as it flies. This procedure enables the satellite to gather a sequence of one-dimensional pixel arrays which, when stacked as rows, form a two-dimensional image.
3.2 Spectral and Spatial Characteristics of Data and Data Volumes

As indicated in Table 1, a wide variety of data of differing spectral and spatial characteristics are gathered from Earth observing satellites. Sensors are generally intended for particular applications and are designed to have the appropriate combination of spectral and spatial characteristics. These characteristics include:

- spatial resolution or pixel size (which may vary across the captured image)
- swath width of the Earth “scene” which is imaged
- number of spectral channels
- location and bandwidth of spectral channels
- quantization accuracy of spectral measurements.

Although it would be ideal to maximize spatial resolution, scene width, number of channels, and quantization accuracy, this can lead to an unmanageable quantity of image data for practical purposes. Excessive data volumes lead to problems in data transmission, storage, and analysis. Sensor designers therefore decide on an appropriate trade-off between the imaging characteristics according to the primary intended application. Gathered data volume is also affected by the repeat cycle of the imaging system.

The VEGETATION sensor flown on board the SPOT-4 satellite is a notable example of an instrument designed specifically for one primary application: the monitoring of global vegetation. It has a spatial resolution of 1.15 km, a swath width of 2200 km, four spectral channels, and high precision 10-bit quantization (i.e. 1024 signal levels in each channel) leading to a sensor data rate of 500 kbit s\(^{-1}\). The locations of the spectral channels are optimized for the detection of chlorophyll and to remove atmospheric influences on the detected ground radiances.

3.3 Orbits and Temporal Repeat Cycles

To investigate dynamic environmental phenomena, remote sensing satellites must be capable of generating images of the same location on Earth on a regular repeat basis. For meteorological applications there needs to be a repeat cycle of the order of a few hours at most. For many land applications, repeat cycles of a few days or even weeks suffice.

Most remote sensing satellites fly in one of two main types of orbit:

- geostationary orbit in which the satellite constantly stays over the same point on the Earth’s surface (this type of orbit is used for some meteorological satellites such as the Geostationary Operational Environmental Satellite (GOES) series – the orbital altitude must be approximately 36 000 km)
- sun synchronous polar orbits in which the satellite orbits approximately from one pole to the other in a constant “vertical” plane whilst the Earth rotates beneath it (typical orbital altitudes of the order of 800–1500 km are common).

Satellites in geostationary orbit view only one side of the globe from a constant (and relatively distant position). They are thus able to generate repeat images by simply rescanning the globe as fast as the optical and electronic systems permit. Satellites in lower polar orbits view only narrow strips of the Earth as they fly (usually in push broom mode) and can only generate repeat imagery when their orbital track brings them back over the same point.

\(^a\) Repeat cycles can be reduced for satellites which permit programmed off-nadir viewing, e.g. the SPOT series.
on the Earth’s surface. In most cases the orbit parameters are designed so that a fixed repeat cycle of a few days or weeks is established. Examples of satellite orbital characteristics and temporal repeat cycles are given in Table 2.

3.4 Imaging Spectrometers

Imaging spectrometers are designed to capture hyperspectral imagery, that is images with a large number of usually narrow closely spaced spectral channels. Such sensors usually provide from at least 15 up to approximately 250 spectral channels. The first satellite-borne imaging spectrometers will be the MODIS sensor to be carried on TERRA and the MERIS sensor to be carried on ENVISAT (Table 1). Imaging spectrometer systems have also been developed for airborne remote sensing such as the GER-63 (Geophysical Environmental Research Corporation 63 channel spectrometer) and the 224 channel AVIRIS (Airborne Visible and InfraRed Imaging Spectrometer) developed by the NASA JPL (Jet Propulsion Laboratory). Imaging spectrometers are of most interest for applications where precise discrimination of surface features is required, such as in ecological or geological studies. Hyperspectral imagery can be regarded as forming a data cube since the multiple spectral measurements effectively add a third dimension to an image pixel array. Imaging spectrometers have the potential to generate very high data volumes. In order to keep data rates within currently acceptable bounds, satellite-borne systems such as MODIS or MERIS will operate only at medium spatial resolution rather than at high spatial resolution.

3.5 Very High Spatial Resolution Imaging

Very high spatial resolution imaging usually refers to satellite images gathered with pixel sizes of $10 \times 10$ m or less. A number of civilian satellites capable of acquiring such images have been developed during the late 1990s, representing a new trend in satellite remote sensing. The origins of this technology lie with earlier military surveillance satellites. Very-high-resolution images are ideal for large-scale mapping (e.g. 1 : 10 000 scale) and for detection and analysis of artificial structures on the landscape.

Several very-high-resolution remote sensing satellite systems are in development by commercial organizations because of the economic potential of detailed land surface observations. Such systems will not gather data continuously because of the very high data rates that would be produced. Instead most very-high-resolution systems are designed to be programmable so that the sensor views a particular chosen ground location as it passes.

4 EARLY STAGES OF IMAGE PROCESSING AND ENHANCEMENT

4.1 Geometric Correction and Geocoding

Raw digital satellite images captured by satellites usually need to be corrected for geometrical distortions caused by sensor aberrations and orbital instability. They also usually need to be transformed to an appropriate map projection and cartographic grid (geocoded) so that they can be integrated with environmental data derived from alternative sources (such as digital maps). This involves transforming an image $I$ with pixel array coordinates $(x, y)$ into a new image $I'$ with pixel coordinates $(v, w)$. The transformation is achieved with a deformation mapping $(M)$, Equation (1)

$$I'(v, w) = M[I(x, y)]$$

The transformed image must be generated at regular integer grid points $(v, w)$. The transformation may involve a combination of scaling, rotation, and translation. The deformation mapping $M$ can be computed exactly if the image distorting function is known. However in most practical cases it is determined by identifying ground control points (GCPs) in the image and in the reference grid and deducing a polynomial function which maps from the image to the reference grid and vice versa. Easily identifiable spatial features such as road intersections, or points on coastlines are usually used as GCPs.

4.2 Noise Removal

Satellite images usually contain noise as a result of the sensing and data transmission processes. This may manifest itself in images as pixel “drop outs” (where the radiance value of an individual pixel has been seriously corrupted). This can be corrected by modifying pixel values which anomalously differ from their neighborhood average. Noise is also manifested as image striping which can be corrected using special purpose algorithms. For some purposes, such as classification, noise can be removed by applying a low-pass filter to an image, which results in local smoothing of pixel radiance values. Filtering can be performed by any of a large number of neighborhood operators, such as the $3 \times 3$ Sobel Operator. Further information on such operators can be obtained from standard image processing and computer vision texts. In some cases, it is desirable to use filters which preserve abrupt changes in image intensity due to edges of real spatial features on the landscape, such as the Nagao–Matsuyama filter for edge preserving smoothing.

SAR images are subject to a special form of random multiplicative speckle noise arising from the coherent
radar imaging process. Individual pixel values by themselves cannot be taken to be indicative of the radar backscatter coefficient of a particular location on the Earth. Speckle filtering must be carried out to estimate the true radar backscatter coefficient of each pixel. A number of algorithms have been developed to remove speckle noise such as that described by Nezry and De Groot.\(^7\) See also Curlander and McDonough\(^3\) for a wider discussion of the SAR speckle phenomenon.

4.3 Spectral Feature Enhancement

Spectral measurements in satellite images are often confined to a narrow part of the overall dynamic range of the sensor's response. It is therefore often useful to expand the measurements to a wider dynamic range as a means of improving the discrimination of surface features. Simple computational techniques can be used to perform this, such as the linear contrast stretch (Figure 3) or the nonlinear histogram equalization technique.\(^5\)

4.4 Principal Components Analysis and Spectral Data Reduction Techniques

It is often difficult for the information content of large numbers of spectral bands in satellite images to be fully comprehended by the user. Techniques have therefore been adopted to concentrate a large proportion of the spectral information into a smaller number of synthetic channels created by applying a geometrical transformation to the initial multidimensioned spectral space. One of the most common approaches is the Principal Components Transform (PCT) which creates a new set of orthogonal axes in spectral space with maximum variance. The first principal component image thus contains more information about the variability of the viewed landscape than any individual spectral channel alone. In very-high-dimensional spectral spaces, the technique of projection pursuit\(^8\) may be used as a search procedure to determine an optimum transformation of the data. This has been applied to hyperspectral imagery.\(^9\) Besides computing principal components, other linear combinations of spectral measurements may be defined to emphasize certain aspects of ground features. A good example is the tasseled cap transform. This can be used to generate synthetic spectral channels to emphasize brightness, greenness, and wetness of land surface features by applying linear weighting factors to the original spectral channels, for example of the Landsat TM sensor of Crist and Cicone.\(^10\)

4.5 Normalized Vegetation Indices

Satellite images are frequently used to study vegetation and estimate surface biomass. The relative amount of green vegetation in a pixel can be approximately deduced by deriving a vegetation index from a combination of different spectral measurements. A commonly used index is the NDVI which is calculated in Equation (2)

\[
NDVI = \frac{NIR - R}{NIR + R}
\]

where NIR denotes reflected radiance in the near-infrared spectral channel and \(R\) denotes the reflected radiance in the red visible spectral channel. The computation of NDVI images can be used as a data reduction technique and a method of emphasizing differences in vegetation cover. The NDVI parameter emphasizes the difference between the near-infrared and red reflectance which has been shown to be a good indicator of live green vegetation with high leaf chlorophyll content. Healthy green vegetation has high near-infrared reflectance (reflection by chlorophyll) and low red reflectance (absorption by chlorophyll). NDVI computation is particularly useful in agricultural remote sensing. Empirical relationships between NDVI and crop yield can be used, for example, to predict end of season harvests.\(^11\)

---

**Figure 3** Simple spectral feature enhancement by contrast stretch.
5 IMAGE CLASSIFICATION

5.1 Classification as a Signal Inversion Problem
The classification of multispectral satellite images is one of the most commonly applied analysis techniques. Classification involves performing a transformation from the numerical spectral measurements into meaningful classes or labels which can describe a landscape. Classification effects a transformation from a physical measurement into a cartographic or thematic description of the surface, for example into terms such as forest, urban area, water surface, apple orchards, and so on. As such, classification can be viewed as a signal inversion process. Many different techniques exist for classification of satellite images, most based on statistical techniques or learning algorithms. These “learn” an association between spectral measurements and class labels from observations of known ground features, so-called “ground truth” information.

5.2 Choice of Spectral Bands, Multitemporal Analysis, and Data Fusion
Ideally, classification of individual pixels or groups of pixels should be performed using as much information as possible from as many sources as are available. In practice this normally means using all of the spectral channel measurements available from a given satellite sensor. However, classification can be improved significantly by using images taken on different dates (the multitemporal approach). Multitemporal images can particularly help to differentiate vegetation classes by virtue of the fact that different species have differences in their phenological cycles which are manifested in varying spectral response curves. For example, deciduous forests can be easily separated from coniferous forests by combined use of summer and winter imagery.

Besides using multitemporal imagery, classification can be improved by using images acquired in different parts of the electromagnetic spectrum by sensors on additional satellites. For example, the combination of optical and infrared imagery acquired by one satellite with radar imagery acquired by another can make a significant overall improvement in the accuracy of a landscape classification. This is an example of data fusion. The process of data fusion can also include the use of ancillary geographical data sets acquired from conventional ground level surveys. Usually the data fusion process is nontrivial because the multiple images or ancillary data sets may have been sampled at different spatial resolutions and stored in different cartographic projections, or as image frames in different orientations. This may necessitate a considerable level of additional image preprocessing. A good review of data fusion in remote sensing is provided by Pohl and Van Genderen.\(^{12}\)

5.3 Per-pixel Approaches and Segmentation
The process of classification and the generation of class labels may be performed either for individual pixels (“per-pixel” approaches) or for contiguous groups of pixels that constitute a meaningful spatial object to which a single class label can be applied. In order to do the latter, an image has to be initially divided into the separate spatial groupings of pixels, a process known as “segmentation”.\(^{13}\) Segmentation can be performed by detecting discontinuities in radiance in an image which delineate the borders of homogeneous land parcels (the edge detection approach). Alternatively it can be performed by finding groups of adjacent pixels which are spectrally similar and locally merging additional pixels to these groups, if they satisfy a spectral similarity constraint (the region growing approach). Both approaches are aimed at dividing an image into a mosaic of landscape parcels which are spectrally similar and therefore likely to define single objects or landscape types which can be classified and labelled. In addition, several hybrid approaches have been developed which integrate and take advantage of both the edge and the region methods.\(^{14}\) The spectral radiance of an entire parcel is obtained by averaging the spectral measurements of each pixel from which it is composed. This averaging process removes the spectral variability of each individual pixel, thus in most cases making the classification of the parcel more accurate.

5.4 Unsupervised Data Clustering
The different spectral radiance values recorded by a typical multispectral satellite sensor can be regarded as independent measurements of properties of the Earth’s surface. As such they create a multidimensional measurement or “feature” space in which all the pixels are scattered. The radiances of pixels corresponding to similar land cover types can normally be expected to be grouped in similar regions of this measurement space (Figure 4). It is therefore often useful to apply clustering algorithms to the data to determine the locations of the most important pixel groupings in the measurement space and so determine the dominant land cover classes in the image. This is usually done by an iterative procedure such as the k-nearest neighbor algorithm.\(^{15}\) Once the dominant data clusters have been found, it is necessary to assign class labels to them in order to attach some physical meaning. In practice this may not be easy as the spectral groupings may not correspond to physical land cover classes in an obvious way. Unsupervised data clustering and subsequent assignment of labels are therefore rarely used as the sole means of classifying satellite image data. Normally ground truth information is used to guide the classification. This is the supervised
rather than the unsupervised approach. However the results of an initial unsupervised classification can be used to guide the selection of representative pixels for a subsequent supervised classification.

5.5 Self-Organizing Feature Maps for Data Clustering
Recently, artificial “neural network” algorithms have also been used for unsupervised data clustering in remote sensing. The self-organizing map neural network algorithm developed by Kohonen\(^\text{16}\) models data using a multidimensional array of competing “neurons” which each learn to represent a prototype cluster from a given data set. The array of neurons effectively becomes a map of the natural relationships between the patterns (spectral measurements) given to the network. Self-organizing networks have been found to be powerful tools for complex pattern recognition problems. In remote sensing they have been found to reveal interesting land surface features in complex data sets.\(^\text{17}\) However their usefulness is not universally agreed upon as it has also been found that they demand excessive computation time in comparison with other methods for data clustering in the remote sensing context.\(^\text{18}\)

5.6 Supervised Classification
Supervised classification is the approach most commonly adopted in remote sensing and one which is often central to the image analysis process since it concerns the direct transformation from measured radiances to thematic map. It is a vital step in the generation of a geographical product from the physical measurements encoded in the satellite images. A good description of supervised classification, together with some excellent practical examples, is provided by Thomas et al.\(^\text{19}\)

The key element of supervised classification of satellite images is to make use of ground truth obtained from a prior field survey to create a reduced set of pixels selected from the image whose thematic classes are known. This reduced set of pixels can then be used to train a classifier algorithm. The objective of supervised classification is then to assign all the pixels in an image to thematic map classes (such as forest, urban area, etc.) by making use of this trained classifier algorithm (Figure 5). Ideally this should happen with a high degree of precision if an accurate map of the landscape is to be produced.

The accuracy of a classification is determined partly by the quality of the ground truth data and partly by how well the restricted set of ground truth pixels is representative of the full image (the “generalization capability” of the classifier). It is also determined by the spectral “separability” of the classes (it is often found that some classes are very similar, for example certain types of vegetation may have very close spectral response curves). In order to measure accuracy, it is common to use only part of the ground truth data for training the classifier algorithm and to use the remainder to test it, that is to see if it produces the classes it is supposed to with the test pixels provided. The results of such tests are normally described in the form of a two-dimensional confusion matrix\(^\text{20}\) which shows how testing pixels from the different classes are distributed by the classifier between all the classes in use. Ideally testing pixels from class N should all be allocated to that same class. In practice, it is rare for more than 80% of the pixels to be allocated correctly
because of the generalization and class separability problems.

5.7 Nonparametric Methods

There are many types of classifier algorithm in use in remote sensing and most commercial software packages used by satellite image analysts offer several alternatives. The objective of training a classifier is to define “discrimination surfaces” which divide the multidimensional spectral space of the image into hyper-regions corresponding to different thematic classes.

The simplest forms of classifier are those which rely on nonparametric methods in which there is no attempt to create a parameterized model of how the pixels of different classes are distributed. In the “parallelepiped” or “box” classifier, simple linear or planar discrimination surfaces are defined in spectral space to define the classes (Figure 6). In the “minimum distance classifier”, class means are first identified in spectral space and then a pixel is simply allocated to the nearest class on the basis of Euclidean distance. This is equivalent to dividing the spectral space by use of a Voronoi tessellation (Figure 7). Sometimes threshold distances from means are used in order to avoid classifying pixels which are spectrally too dissimilar from any of the available classes.

5.8 Parametric Approaches

As seen in Figures 6 and 7, nonparametric methods usually rely on simple planar discrimination surfaces to define a classifier’s behavior. This is a relatively crude approach, especially when the pixels corresponding to a class are distributed in an irregular or nonsymmetric manner. Parametric approaches to classification make use of parameterized models of the classes in the spectral feature space. These are generally much more powerful than nonparametric methods and lead to higher overall classification accuracy.

5.9 Statistical Classification and the Maximum Likelihood Method

The most common parametric approach is to use a statistical method and to model classes according to the distributions of the training pixels. Most often classes are modeled by using the multivariate form of the normal probability density function. Pixels are then classified by assigning them to the class to which they have the highest statistical likelihood of belonging. This approach effectively results in classes being discriminated on the basis of ellipsoidal equiprobability surfaces in the spectral feature space (Figure 8).

5.10 Neural Network Classification: Multilayer Perceptrons

Since the late 1980s, supervised classification of satellite image data has also been performed by artificial neural network algorithms which have rapidly gained in popularity for satellite image analysis. In supervised classification, their layers of interconnected processing elements are trained to perform a mathematical transformation between spectral radiances and thematic map classes.

The most common type of neural network adopted in remote sensing for supervised classification is the multilayer perceptron (Figure 9) which is trained by
Figure 8 Maximum likelihood classification. The classifier models each class by a normal distribution which can be represented as concentric equiprobability contours in the spectral feature space. Pixel X has a higher probability of being in class C than class B even though in spectral distance terms it is closer to the mean of class B.

Figure 9 Multilayer perceptron neural network classifier. Such a network can be trained to encode a mathematical transformation between spectral values and their thematic class associations. The nodes in the network are linked by connections which carry weighting factors. Each node performs a nonlinear mathematical operation on its inputs to derive its own output which it passes on to other nodes. The network is shown partially connected for clarity. Usually such a network has connections between all nodes in successive layers.

the backpropagation algorithm. A good review of this technique can be found in Paola and Schowengerdt.(24) They have often been found to perform as well as statistical classifiers in terms of overall classification accuracy. Their popularity as a classification technique in remote sensing can be partly attributed to the fact that they do not make any initial assumptions about the form of the distribution of the satellite data and appear well suited to fused data sets comprising images from multiple sources. The main disadvantage of the technique is that training can be a long procedure sometimes requiring several hours of computer processor time, depending on the number of pixels, spectral channels, and classes, apart from the size of network selected.

5.11 Combined Classification Approaches and Soft Classification

Since statistical and neural network classification approaches have different strengths and weaknesses, some attempts have been made to integrate them, for example by Wilkinson et al.(25) The essence of this integrated approach is to use both statistical and neural classifiers in parallel and then to reclassify any pixels for which they disagree. The reclassification is performed by a second neural network which is trained specifically to deal with “difficult” pixels (usually outlier pixels on the edge of the main class clusters).

In some cases, it may be difficult to assign pixels in satellite images to single thematic classes because they contain a mixture of land cover types. They are hence regarded as mixed pixels. Various methodologies have been developed for “soft” classification of such mixed pixels.(26) These are mainly concerned with fuzzy set approaches in which pixels may have partial membership of more than one class.

5.12 Alternatives to Classification: Spectral Mixture Modeling

Spectral mixture modeling is an alternative method of describing mixed pixels. Instead of being interpreted as a mixture of thematic land cover classes, pixels are regarded as a mixture of pure spectral signatures of certain types of reflecting terrestrial surface (e.g. bare soil, bright green vegetation, dry senescent vegetation). Normally these signatures are chosen to be at the extremities of the spectral measurement space and are known as end-member spectra. Each pixel can then be given a labeling which specifies its relative abundance of each end-member spectral component. For this technique to provide unique labelings, the number of end-member spectra used cannot exceed the number of independent spectral channels plus one. Bastin(27) compares spectral mixture modeling to both maximum likelihood classification and fuzzy classification and concludes that fuzzy classification gives the best prediction of subpixel land cover areas. However the
extraction of subpixel information is currently the subject of continued research.\(^{(28)}\)

## 6 CLASSIFICATION REFINEMENT

### 6.1 Spatial Smoothing and Rule-based Postprocessing

Classification by itself generates thematic image products which usually contain some degree of error. This is often manifested as scattered pixels which are labeled with quite a different class to their immediate neighbors. This kind of error can be removed to a large extent by applying filtering or spatial smoothing operations to classification products. Such postclassification refinement can be performed using, for example, spatial context information or rules about expected class occurrences stored in a knowledge-based system.\(^{(29)}\)

### 6.2 Structural Scene Models and Use of Textural Analysis

As spatial resolutions of satellite images have improved, there has been growing interest in the detection and classification of visible structural features on the Earth’s surface such as geological lineaments and artificial objects. The classification of such features can be of enormous benefit in applications such as mineral prospecting and topographic mapping in remote areas. This generally requires the use of computational models to describe such objects and “intelligent” algorithms to detect them. A good state of the art survey of recent results in this field is provided by Gruen et al.\(^{(30)}\)

Classification of images may also be improved by using the image “texture” in the vicinity of a pixel, determined by the local spatial variability of the spectral radiances. Local texture parameters may be computed for each pixel in an image and used as additional spectral feature channels in the classification process. The texture measures described by Haralick et al.\(^{(31)}\) are commonly used in satellite remote sensing for this purpose.

More satellites monitoring some aspect of the Earth are launched each day. This article gives an overview of the science and practice of remote sensing (RS). It goes into the technical details of the physics behind RS, lists some typical contemporary and future Earth observing (EO) satellites, and explains the factors that determine the quality of images from space. This relatively short article cannot cover the entire field of RS, but the references and further reading list can be used for further study.

1 INTRODUCTION

One could argue that RS dates back to the invention of Aristotle’s camera obscura. However, practical RS started after the invention of a stable photographic process by Niéce and Daguerre, who published their results in 1839. Soon enough, cameras were carried on-board virtually everything that could fly, from hot-air balloons to kites and rockets. The images thus returned by cameras offered an unprecedented view of the Earth and our environment. Large patches of land could be imaged by just a few photographs.

However, this unique viewing capability also poses a challenge in interpreting these images. For one thing, vertical viewing is completely different from normal viewing, providing a very different perspective than what we are familiar with. Usually the sense of depth is lost when viewing a single photograph. The combination of an unfamiliar perspective with a very different scale and lack of recognizable detail can make the most familiar object unrecognizable in an image. Another problem is that our eyes are limited in the spectral sense, being sensitive to only a very small wavelength range, between roughly 400 and 700 nm, the so-called visible part of the spectrum, and the representation of wavelengths outside this window is more difficult for us to comprehend. The interpretation of radio detection and ranging (radar) images, again, are more difficult to interpret, because the way in which radar waves interact with materials requires rethinking the process of how we see objects with radar. All this, the sensors, the platforms, and the interpretation, justify the following definition:

RS is the science of acquiring, processing, and interpreting images that record the interaction between electromagnetic energy and matter.\(^{(1)}\)

RS has also been called an “art”,\(^{(2)}\) obviously because it requires skills and experience to interpret RS images. Major uses of RS images include:

- weather observation and prediction
- topographic mapping
- coastal zone management
- oceanography
- minerals, oil and gas exploration
- agricultural monitoring
- environmental monitoring
- education

- intelligence gathering

1.1 The Remote Sensing System

The term “RS activities” means the operation of RS space systems, primary data collection and storage stations, and activities in processing, interpreting and disseminating the processed data. The last definition comes close to defining RS as a closed system, consisting of the following components (see Figure 1).

1.1.1 The Scene

Any object on Earth. Objects are roughly classified as land, ocean, and atmosphere objects, because measurement devices typically are tuned for the measurement task at hand. Usually these three different classes require different types of instruments, although that does not mean that the data from one such type of sensor cannot be used for other purposes.

If the images cover a large part of the Earth, knowledge of the shape and movement of the Earth is also required for the interpretation of the images.

1.1.2 The Energy Source

In principle, the whole spectrum of electromagnetic radiation is available for acquiring information about the object, but in practice only limited parts of the spectrum are used.

In fact, the RS of other sources of energy and fields is possible, such as the measurement of radioactive decay and the magnetic and gravitational field. However, the discussion of these types of measurements is outside the scope of this article.

1.1.3 The Atmosphere

Although good for breathing, the atmosphere is a source of unwanted effects in RS images. Energy is added to, or subtracted from, the signal coming from the object, making atmospheric corrections necessary if absolute measurements are required. Furthermore, various gases of the atmosphere are the cause of its opacity in some of the frequency bands in the electromagnetic spectrum. The frequency bands that are transmitted are the so-called atmospheric windows. Most of the spectral bands used by remote sensors fall entirely within these atmospheric windows, unless, for instance, the absorption itself is an indication of the abundance of certain constituents of the atmosphere. A minor effect of the atmosphere is the displacement caused by refraction.

1.1.4 The Remote Sensing Instrument

The RS instrument can be any type of sensor. Treated in this article are the so-called imaging sensors, sensors that yield two-dimensional data from the Earth. Typically, the remote sensors operate in the ultraviolet (UV), the visible, the infrared (IR), the thermal IR, and the microwave parts of the spectrum. Note that the sensors operating in the optical part of the spectrum, i.e., that part of the spectrum where the energy can be manipulated by optics (extending from roughly 0.3 to 14 µm), can be divided into the optical system, and the detectors themselves. Both subsystems can give rise to their own type of errors. Also note that by the term “instrument” we usually mean the entire device, whereas “sensor” means only the detector and electronics part. However, these terms are commonly loosely interchanged and used for indicating the same thing: the imaging device.

1.1.5 The Platform

As mentioned before, remote sensors can be flown by any type of platform. This article focuses on airborne RS, but mostly RS by spacecraft. These artificial satellites are launched by rockets and brought into orbit with the help of complex celestial mechanics. Users of RS data usually need not be bothered with how this is actually done and, except for some considerations about minor orbit corrections and attitude control, nothing will be said about this here. The most important factor for the spaceborne platform is its final orbit, as each type of orbit has its own advantages and disadvantages. The height of the orbit clearly determines the details that can be discriminated by the sensor. Its inclination determines the percentage of the Earth’s surface that can be imaged, and various parameters together determine the repeat cycle of the orbit and this in turn will determine how often a sensor will be able to take an image of a certain location on Earth. This and more will be discussed in one of the following sections.
1.1.6 The Command and Receiving Station(s)
Left to itself, the satellite will quickly drift from its predetermined orbit, lose its attitude, and may finally be unrecoverable altogether. The satellite has to be taken care of, its status must be checked on a daily basis, and commands must be sent to the satellite to take corrective actions. Furthermore, the sensors must be programmed as to where the next images will be taken. The satellite can transmit the data it records in real time to a ground station, but then a station must be within reach of the satellite. With practical downlink technology, this means that the satellite must be within sight (in the “line of sight”) of the ground station. Clearly, this requires having ground stations all around the globe to obtain global coverage. There are two ways to overcome the need for having many ground stations. One way is to carry a mass-memory device on-board the platform, so that images can be recorded and played back off-line later when the satellite is over a receiving station. Another way is to relay the data from the RS satellite via communication satellites to the ground. All possibilities are currently being used and have their own specific advantages and disadvantages.

1.1.7 The Archiving Facility
The bytes keep raining to the ground by the megabyte, and most of the information is stored somewhere for possible later use. Some archiving centers already have hundreds of terabytes in their archives, and it is growing daily. What do we do with all these data? These archives are a great source of data for global change detection. But to what lengths should we go to maintain these archives? Already today complete archives of images recorded on microfilm are abandoned, simply because it is too expensive to keep them! Modern systems may even suffer from the fact that there is no archive of previously recorded data from the same sensor. The new images may be incompatible with older sensors, making a comparison very hard, if not impossible.

1.1.8 The Processing and Interpretation
The processing and interpretation of RS data is an essential part of the RS activities, without which most of the data would be virtually worthless. The purpose of the analysis is to transform the data to higher levels of information in order to make the result useful for the application at hand. The processing itself can be divided into three categories, although there is not really a sharp distinction between them. Preprocessing corrects for systematic and random errors. Image processing is a set of techniques for manipulating digital images, the result always being an image. In image analysis, the result of the processing may no longer be image data, but some form of information.

1.1.9 The Dissemination of the Data
The information is then disseminated directly or via resellers to the end-users. Currently there is a blooming market of value-added resellers, who buy and process data for third parties.

1.1.10 The Management of the Earth
The ultimate goal of all these information-gathering activities, of course, is to use the knowledge thus acquired to our advantage for managing the Earth. Many of the RS systems are currently used for monitoring, just watching for changes, not for direct action. Most of these management processes are slow processes, and the fact that RS is part of a closed system is not always as obvious as, for instance, using a computer vision system in a brewing company for removing bad bottles from a conveyor belt. However, some tasks do require a quick response, such as fire detection or any other form of disaster monitoring. Such tasks require near real-time dissemination of the data and, unfortunately, this is, as yet, not the case for most of the traditional land RS systems. There is one prominent exception to this rule, namely meteorology. Meteorologists have a long history of global distribution of all kinds of data in real time across global networks, including satellite imagery. Meteorologists were the first to understand that satellite-based observations “see between the cracks” of ground-based observations, providing the earliest clues to the onset of the potential development of severe weather.

In the RS system as defined above, the data flow changes from low-level data to high-level information in a number of steps. Usually the following types of data are distinguished.

1.1.11 The Primary Data or Raw Data
The term “primary data” means the raw data that are acquired by remote sensors borne by a space object and that are transmitted or delivered to the ground from space by telemetry in the form of electromagnetic signals, by photographic film, magnetic tape, or any other means.\(^{(3)}\)

1.1.12 The Processed Data
The term “processed data” means the products resulting from the processing of the primary data, needed to make such data usable.\(^{(3)}\) With processed data we simply mean the satellite images that we mostly encounter.
1.1.13 Analyzed Information

The term “analyzed information” means the information resulting from the processing and interpretation of data, inputs of data and knowledge from other sources, where a distinction can be made between processing by a computer, and interpretation by a human operator. In practice, this distinction is not a clear one as computers are heavily used in RS and in most applications the touch of a human operator is still needed to drive the process of retrieving information. Analyzed information comes in many forms. One important form is digital data that can be ingested by information systems, usually consisting of a database and a set of tools for manipulating the elements in the database for further analysis.

Tools for the analysis and presentation of the information acquired by RS have traditionally been in the separate fields of photogrammetry, image processing, geoinformation systems (GIS), and cartography, but recently these fields have merged and many software packages have emerged that have strong capabilities in all fields. Such software enables the user to process the data from beginning to end, from raw data to high-quality output maps and information.

The discussion of GIS and resource management information systems is outside the scope of this article, but details can be readily obtained from standard works such as those by Aronoff and McCloy.

The task of producing a useful information product from the primary data is not a trivial one and requires many processing steps and knowledge about the object, the Earth, the source of energy, the atmosphere, the remote sensor, and the platform. Most of these themes will be discussed in the following sections.

2 HISTORICAL OVERVIEW

At the end of World War II the Germans used their V2 rockets to bomb cities in Belgium and the UK. Very few people would have guessed that these terrible weapons would be used shortly after the war for a much nobler goal: to gain knowledge of the upper atmosphere and solar radiation. About 100 confiscated V2s (together with German scientists and engineers such as Dr Wernher von Braun) were transported to the USA and launched successively during the following 5 years. Instead of explosives the nose of the rocket now contained scientific instruments for measuring the chemical composition of the atmosphere, for measuring wind speed, for measuring electric and magnetic fields, and for solar and cosmic radiation. Sometimes these rockets would also carry photographic cameras, for taking pictures of the Earth and the solar spectrum. It was difficult to retrieve the cameras in one piece, so soon the images were transmitted back to the Earth during the flight. Around 1950 the stock of V2s became exhausted and the USA started to build its own rockets. In the former USSR similar developments were going on. During the “Cold War” this took the form of a rocket-building competition. Of course, this way of monitoring the Earth and the Sun has disadvantages. The time for one observation using a rocket is short; the time above 80 km was typically less than 2 min. The cost of the launch with respect to the observation time was very high. It was nowhere near a continuous observation of interesting phenomena. The idea was launched of developing a “long-play” rocket, one that would be launched to a certain height and circle the Earth at such a speed that it would “fall” around the Earth in a circular orbit. The required speed at the surface of the Earth would be 7.9 km s⁻¹; at 500 km high the speed would be 7.6 km s⁻¹. To launch a satellite in such a circular orbit is a very complex problem, requiring a profound knowledge of orbital mechanics. Then the satellite needs to have instruments that will be able to operate in the harsh space environment, and the signals of the instruments must somehow be received on Earth in order to obtain the data from the instruments. Another problem is the atmosphere of the Earth. The satellite should fly high enough in order not to experience the drag of the atmosphere. However, even at a 300-km height the satellite will experience some drag. It will slow down over time and eventually, after months or even years, at a 90-km height it will be heated by friction with the air and totally burn before it hits the Earth’s surface.

The first practical realization of this idea of artificial satellites occurred on 4 October 1957, when the Russians launched their Sputnik I. A second, much larger, Russian satellite followed on 3 November 1957. The first American satellite, Explorer I, was launched on 31 January 1958.

The Space Age probably started with the theoretical basis for rockets developed by Hermann Oberth and Robert H. Goddard directly after World War I, and reached its apotheosis on 20 July 1969 when Apollo 11 landed on the Moon. Neil Armstrong was the first human being to set foot on the Moon. As he placed his left foot on the dusty surface, a breathless world could just distinguish his words: “That’s one small step for a man, one giant step for mankind”.

The main disappointment of the Apollo program was that, after Apollo 17, humankind seemed as far as ever from understanding the origin of the Moon. The first Moon landings, the technical mastery of space travel, and the final scientific expeditions to the lunar surface must nevertheless rank as the most significant step so far in humanity’s development.

In the meantime, space was already being used for communication and observation. Systematic satellite
observations of the Earth began in 1960 with the launch of Television and Infrared Observation Satellite (TIROS) 1, the first meteorological satellite, using television tubes as a low-resolution imaging system.

Beginning in the mid-1960s, a large number of studies of the application of color IR and multispectral (MS) photography were undertaken under the sponsorship of the National Aeronautics and Space Administration (NASA), leading to the launch of a MS imager on the Earth Resources Technology Satellite (ERTS) 1. ERTS-1 was later renamed Landsat 1; it was to be followed by four more Landsat satellites in the 1970s and 1980s.

In 1981, the Space Shuttle provided a new platform for remote sensors. The second Shuttle flight carried a package of Earth-oriented sensors including imaging radar, a MS radiometer, and a visible ocean color scanner.

Radar work expanded dramatically during World War II. Today, the diversity of applications of radar is truly startling. It can be used for mapping the topography of the ocean floor, for atmospheric phenomena, for surface structures, for subsurface structures, and for measuring height and wind speed. Radar sensors can be configured in many different modes, including altimetry, scatterometry, synthetic aperture radar (SAR), polarimetry, and interferometry.

A more recently introduced RS instrument is the light amplification by stimulated emission of radiation (laser), which was first developed in 1960. It is mainly being used for atmospheric studies, altimetry, and surface studies using fluorescence.

One more technology that is waiting to become spaceborne is hyperspectral imaging. Hyperspectral imaging or imaging spectrometry takes images in many narrow contiguous spectral bands, as opposed to the MS systems that take only images in a few broad bands. Unfortunately, the first attempt to launch a civil imaging spectrometer failed in 1997, when NASA’s satellite Lewis went out of control and burned in the atmosphere.

RS has also expanded dramatically using planetary spacecraft. Images were acquired of the surfaces of the Moon, Mercury, and Mars and the atmospheres of Venus, Jupiter, Saturn, and Uranus. Currently, other objects are also under investigation such as the Sun, asteroids, and comets. Further, there is renewed interest in the Moon, Mars, and the Jovian moons. Although the RS satellites and the planetary probes have many things in common, there are also many differences. The probes will not be discussed here.

In the next millennium large platforms, such as the International Space Station (ISS), may be used as the host for an array of sophisticated sensors that can be replaced periodically by more advanced types when they become available. Major advantages of such a platform are that it will be permanently inhabited, which means that instruments can be serviced whenever necessary, and sensors can be pointed manually at, for instance, disaster areas.

Throughout the Cold War, the USA and the former Soviet Union viewed control of satellite RS paramount to holding an intelligence “high ground”. The race to space was on. The end of the Cold War produced major changes in government policies restricting the development of new RS capabilities.

At the time of writing, RS is at the brink of a new era. One revolution is the commercialization of high-resolution RS satellites. In 1994, the US government decided to allow the civil commercial development of RS satellite systems providing higher spatial resolution, with up to 1-m resolution. They were afraid that the presumed US leadership in civil satellite RS would erode further if other countries were to develop the 1-m data market first. Several US companies are engaged in a new race to space, trying to be the first in space with a high-resolution sensor.

In general, one can say that the trend is towards “high resolution”: high spatial resolution, high spectral resolution, high radiometric resolution, and high temporal “resolution”. The last item, the capability to revisit areas frequently, can also be achieved by RS satellite constellations. The current miniaturization trend for satellites makes that possible. Already at this time 10 microsatellites can be built and launched for the price of one traditional satellite. Smaller satellites can be launched riding piggyback with other microsatellites on a larger satellite. Problems such as shielding, attitude control, and controlling a constellation, instead of a number of individual satellites, will eventually be overcome and pave the way for another boom in space exploitation.

Table 1 lists some highlights of the first Earth images from space.

3 PHYSICAL PRINCIPLES OF REMOTE SENSING

3.1 The Electromagnetic Spectrum

From the previously mentioned definition of RS, it is clear that the knowledge of the electromagnetic field is important for the interpretation of RS images. This section deals with some of the properties relevant for RS. The physical nature will be discussed, in addition to the interaction of electromagnetic radiation with various materials and surfaces. All this is needed to understand what an object will look like in a RS image.

3.1.1 Electromagnetic Energy

Electromagnetic radiation is a form of radiation in which energy is carried by oscillating electric and magnetic fields, which move together and travel through space at the speed of light. Electromagnetic radiation is generated by the acceleration of an electric charge, for example, by the movement of electrons in an antenna. The electric and magnetic fields can be thought of as oscillating at right angles to one another as they move together through space. In the 19th century, James Maxwell developed a set of equations that describe the behavior, with the changing electric field producing the changing magnetic field. The equations include a constant \( c \), which is the speed of light at which the waves move through empty space. It turned out that this constant is precisely the speed of light, proving that light is a form of electromagnetic radiation. Electromagnetic radiation can also travel through some media, at a slightly slower speed than \( c \).

The entire spectrum, from \( \gamma \)-rays to longwave radio waves, is explained by Maxwell’s equations, with the appropriate wavelength for the radiation. Quantum theory also describes the radiation in terms of a stream of particles, called photons; each quantum of radiation with a particular energy \( E \) is Planck’s constant, \( 6.63 \times 10^{-34} \). \( \gamma \)-Rays are the most energetic and radio waves the least energetic.

In terms of the quantum description, photons behave like particles obeying Bose–Einstein statistics (bosons). Our everyday experience makes it hard to understand how something can behave as both waves and particles, yet many experiments have shown that this is just the way the quantum world works, and physics uses whichever description is convenient. Blackbody radiation, a term explained below, can be described perfectly in terms of photons as a “gas” of bosons.

It should be noted that electromagnetic radiation is sometimes expressed as having a frequency, sometimes as having a wavelength \( \lambda \), and another time as having a particular energy. Frequency \( f \), wavelength \( \lambda \) and energy \( E \) are directly related to each other by the simple Equations (1) and (2):

\[
c = f \lambda \quad (1)
\]

\[
E = hf \quad (2)
\]

Two beams of light (or any other form of electromagnetic radiation) are coherent when the phase difference between their waves is constant. This can only occur if both beams are of exactly the same wavelength. They are noncoherent if there is a random phase relation. In active systems such as radar and laser, the term coherence means that in addition to the amplitude (intensity) of the reflected beam, the phase can also be measured. The phase can be used for measuring small differences in height. The phase difference \( \Delta \theta \) as a result of a difference in height \( \Delta h \) can be expressed by Equation (3):

\[
\Delta \theta = \frac{2\Delta h}{\lambda} \quad (3)
\]

Height differences of less than one wavelength \( \lambda \) can be measured. By combining the phase information from different observations the topography of the terrain can be reconstructed, and even small displacements of the order of a few centimeters can be measured. The technique of combining the phases of two or more observations is called interferometry. INSAR (also referred to as IFSAR) has been used to visualize depressions or bulges in the terrain caused by earthquakes and active volcanoes. In the future, INSAR may be used as an additional tool for predicting earthquakes or volcanic eruptions by monitoring changes in height.

The Doppler effect is the observed increase or decrease in frequency when the source moves towards or away from, respectively, the observer. Everybody knows the Doppler effect from the lowering of the pitch of the siren when a fire engine passes at high speed. In imaging SAR the Doppler effect, caused by the fast movement of the satellite along the objects, is used to determine whether an object is before, next to, or after the satellite. By cleverly combining all these signals, a better spatial resolution can be achieved, even if the radar antenna is short.

Polarization defines the orientation of the electric field of an electromagnetic wave. Horizontal (H) and vertical (V) polarization refer to the electric field vector being parallel and normal, respectively, to the surface of the medium upon which the wave is incident.

A radar beam can be transmitted horizontally polarized, and the beam can be received horizontally polarized (HH); the beam can be transmitted horizontally and received vertically (HV); the beam can be transmitted vertically and received vertically (VV); or the beam can be transmitted vertically and received horizontally (VH).
HH and VV are called the like-polarization modes and HV and VH are called the cross-polarization modes. If a beam were transmitted horizontally polarized, one would not expect a material to return the signal vertically polarized. Obviously, if this happens, it tells us something about the material. Polarization offers yet another possible way for identifying materials on the surface of the Earth.

The fact that reflected radiation from smooth surfaces is highly polarized can be used to reduce the amount of glint in, for instance, wide-field oceanographic images.

3.1.2 The Spectrum

The most familiar example of a spectrum is the rainbow spectrum of visible light, which can be displayed using a prism or seen in a rainbow itself. White light is made up of a mixture of wavelengths. The spectrum of colors seen by the human eye covers a range from red (with the longest wavelength of about 700 nm) through orange, yellow, green, blue, and indigo to violet (with the shortest wavelength of about 400 nm). The brightness of each color in the spectrum shows how strongly that component of white light contributes to the overall brightness of the source. The properties of the spectrum can be determined accurately either photographically or using electronic detectors. The spectrum extends well beyond the visible range (VIS) at both ends, into the UV and beyond and into the IR and beyond. Usually the IR part of the spectrum is divided into the near-infrared (NIR) (around 1 µm wavelength), the short-wave infrared (SWIR) (around 2 µm), the mid-wave infrared (MWIR) (around 4 µm), and the thermal infrared (TIR) (around 10 µm). Well beyond the TIR region is the microwave range, at wavelengths between roughly 1 mm and 1 m. Most of the Earth observation satellites have detectors that operate in the above-mentioned wavelength ranges (UV, VIS, NIR, SWIR, TIR, and microwave). The combined VIS and NIR range is sometimes designated the visible and near-infrared (VNIR) range. The far-infrared (FIR) range, located between the TIR and the microwave regions, is hardly ever used for RS, simply because the atmosphere is opaque for these frequencies (see section 3.1.5). The microwave range has its own codes for designating the bands (according to the IEEE 521-1984 standard) (Table 2). However, it must be said that these are old codes used in the communications industry, and microwaves are best expressed in frequency or wavelength.

3.1.3 Blackbody Radiation

An object that absorbed all the electromagnetic radiation that fell on it would be a perfect blackbody. Blackbody radiation is the radiation that would be produced by such a hypothetical object when it was warmed. Although a blackbody is an idealized concept, the radiation emitted from objects can be approximately described in terms of equivalent blackbody radiation. All matter at temperatures above absolute zero (0 K) continuously emits electromagnetic radiation. The Sun, for example, radiates rather like a blackbody with a temperature of about 6000 K. Most objects on the Earth have a temperature around room temperature. Hence the radiation emitted by these objects can be approximated by a blackbody of 300 K temperature.

The total amount of energy radiated by a blackbody is expressed by the Stefan–Boltzmann law, which states that the energy is proportional to $T^4$. Therefore, the energy increases very rapidly with increase in temperature. An object at 6000 K radiates 160 000 times more energy than the same object at 300 K. The shape of the curve, with respect to wavelength, is given by Planck’s law (see Figure 2). Two things are obvious: First, the height of the curve increases with increase in temperature and the energy radiated is proportional to the area under the curve; and second, the top of the curve shifts to shorter wavelengths and more energy is radiated at the shorter wavelengths.

![Figure 2](image-url)
wavelengths. This is why a warm lump of iron radiates invisible radiation, a slightly hotter lump of iron glows red, an even hotter lump glows white hot, and eventually it will glow bluish white. The top of the curve first shifts into the red part of the spectrum and moves towards the blue part with increasing temperature. This shift is determined by Wien’s displacement law, which states that the wavelength at which the blackbody radiation curve reaches its maximum is inversely proportional to the temperature (Equation 4):

$$\lambda_{\text{max}} = \frac{A}{T}$$  \hspace{1cm} (4)

where \(\lambda_{\text{max}}\) = wavelength of maximum spectral radiant exitance in micrometers, \(A = 2900 \mu\text{m} \text{K}\) and \(T = \) temperature in kelvin.

The peak of the 6000 K curve of the Sun is located in the middle of the visible part of the spectrum. This may not come as a surprise, because the evolutionary adaptation of the detectors in our eyes will have tuned these in such a way that they are most sensitive to the energy that is abundantly available, sunlight.

The peak of the 300 K curve of objects at room temperature, the approximate ambient temperature of the Earth, is located around 10 \(\mu\text{m}\). As this type of radiation is strongly related to the temperature of objects, this part of the spectrum is called the TIR.

As passive remote sensors measure reflected radiation from the Sun, or measure energy emitted by the object itself, most of the sensors operate in the VIS and TIR parts of the spectrum. However, there are many interesting absorption, reflection, and emission features present in the NIR, the SWIR and the MWIR regions, which explains the many sensors operating in this part of the spectrum. Examples of these features are the high reflection of vegetation in the NIR region, the absorption dips of certain rock minerals in the MWIR region, and fire detection: a fire usually has a temperature of about 1000 K, and has peak radiation around 3–4 \(\mu\text{m}\), in the MWIR region. This means that areas with fires stand out as bright spots on the satellite images taken in the MWIR region, and can be easily detected.

3.1.4 Absorption, Emission, Reflection, Transmission, and Refraction

Although the concept of a blackbody is a way to describe ideal radiation principles, real materials do not behave as blackbodies. Instead, all materials emit less than the energy emitted from a blackbody at the equivalent temperature. The ratio of the real energy radiated by the material over the energy that would be radiated by a blackbody at the same temperature is referred to as the material’s emissivity, \(\varepsilon\). By definition, \(\varepsilon\) will have values between 0 and 1. The emissivity, just like reflection, may have different values for different wavelengths \(\lambda\) and viewing angle \(\theta\). Furthermore, depending on the material, emissivity can vary with temperature. If a material has an emissivity that is constant for all wavelengths, it is called a graybody.

Water comes close to being a blackbody in the 6–14 \(\mu\text{m}\) TIR range, with an emissivity of 0.98–0.99. We have seen that a blackbody is both a perfect absorber and a perfect radiator. This is true in general, and is expressed by Kirchhoff’s law, which states that the spectral emissivity of an object equals its spectral absorbance (Equation 5):

$$\varepsilon(\lambda) = \alpha(\lambda)$$  \hspace{1cm} (5)

This means that good absorbers are good emitters. The emissivity factor must be taken into account if one wants to determine the temperature of objects. In the TIR range the emitted radiance is usually expressed as a temperature. As objects radiate less energy than blackbodies, their apparent temperature, or brightness temperature, is less than the real temperature, or kinetic temperature, of the object. Bearing in mind that the energy is proportional to \(T^4\), it can be shown that Equation (6) holds:

$$T_{\text{measured}}^4 = \varepsilon T_{\text{real}}^4$$  \hspace{1cm} (6)

To understand the reflective properties of surfaces, we have to make a distinction between a perfect specular reflector and a perfect diffuser. Specular reflection is the mirror-like reflection of a smooth surface, where the angle of incidence equals the angle of reflection. Just as we learn little from the mirror by looking at the mirror – we see ourselves – RS usually is not interested in the specular type of reflection. Mostly this type of reflection gives rise to unwanted effects, such as “hot spots” and glint in images, and precautions must be taken not to see this. For instance, wide-angle oceanographic sensors must be pointed away from the specular reflection of the Sun on the water surface, in order to avoid overload of the sensor and sea glint in the images.

Diffuse reflection is the matte reflection of a rough surface. A perfect diffusing surface backscatters the incident radiance in all directions according to Lambert’s cosine law. Lambert’s law states that the radiant energy of a diffuse surface varies with the viewing angle (Equation 7):

$$I = I_0 \cos \theta$$  \hspace{1cm} (7)

where \(I_0\) is the intensity along the normal to the surface and \(I\) the intensity along the line at an angle \(\theta\) with the normal.

As there is no sharp boundary between a smooth and a rough surface, real materials exhibit a combination of the
specular and diffuse reflection properties. To make things worse, real materials are not perfect diffusers. In fact, the reflecting properties of materials can only be measured in the field, and are a function of the angle of incidence of the radiation and the viewing angle. This function is called the bi-directional reflectance distribution function (BRDF), and usually shows a smooth transition between the specular and diffuse reflection properties of a material. The BRDF depends on wavelength and is determined by the structural and optical properties of the surface, such as shadow casting, multiple scattering, mutual shadowing, transmission, reflection, absorption and emission by surface elements, facet orientation distribution, and facet density.

In addition to absorption, reflection, and emission, materials may also transmit energy, passing part of the radiation unharmed. The ratio between the energy hitting the surface and the energy passed by the material is called the transmission, \( \tau \). For preservation of the total amount of energy, Equation (8):\(^{12}\)

\[
\alpha(\lambda) + \rho(\lambda) + \tau(\lambda) = 1
\]

states that the absorptance, reflection, and transmission add up to 1.

For thermal radiation remember that the absorptance and emissivity may be freely interchanged. Furthermore, most objects in RS are assumed to be opaque to thermal radiation (Equation 9):

\[
\tau(\lambda) = 0
\]

such that we can write (Equation 10)

\[
\epsilon(\lambda) + \rho(\lambda) = 1
\]

This shows that the lower an object’s reflectance, the higher is its emissivity, and vice versa, the higher an object’s reflectance, the lower is its emissivity. For instance, water has a nearly negligible reflectance in the thermal spectrum, and as a result it has an emissivity of almost 1.

Furthermore, the material changes the direction of the transmitted energy beam. Snell’s refraction law expresses the relationship between the incident geometry and the transmitted geometry, and depends on the speed of light in both media (Equation 11):

\[
\frac{\sin \theta_i}{\sin \theta_r} = \frac{c_0}{c}
\]

where \( \theta_i \) is the angle of incidence, \( \theta_r \) is the angle of refraction, \( c \) is the speed of light outside the material, and \( c_0 \) is the speed of light in the material.

The ratio \( c_0/c \) is also known as the refractive index, \( n \).

For certain materials, the speed of light \( c_0 \) is a function of the wavelength \( \lambda \), causing the angle of reflection to differ slightly for different wavelengths (colors) in the VIS. This causes the incident beam of mixed wavelengths to be broken up into a fan of split wavelengths. This effect is called dispersion, and can be used to unravel a mixed beam of light, composed of many wavelengths, into its components. An example of such a device is, of course, the prism, which is capable of splitting white light into a rainbow of pure colors.

Other dispersive elements, but based on a different principle, are gratings. Gratings are polished surfaces with a large number of equidistant, parallel grooves. Dispersive elements are used at the heart of imaging spectrometers.

3.1.5 Atmospheric Effects

Like any other material, the constituents of the atmosphere absorb, transmit, reflect, and refract the energy passing through it. Also, the atmosphere, because it has a temperature above 0 K, emits energy by itself. Carbon dioxide, water vapor, and ozone dominate the interaction of the atmosphere with electromagnetic radiation.\(^7\)

3.1.5.1 Absorption Carbon dioxide (CO\(_2\)), absorbs energy near the wavelengths 2.01, 2.08, 4.3, and 15 \( \mu \)m. CO\(_2\) plays an important role in the energy budget of the Earth and its atmosphere, and is known to be a “greenhouse” gas.

Water vapour (H\(_2\)O), is particularly important because of the strong absorption lines in the IR and microwave regions. Water vapor concentration is highly variable in space and time, and may vary from \( 10^{-2} \) g m\(^{-3} \) in a very cold and dry climate up to 30 g m\(^{-3} \) in hot and humid regions.\(^7\) However, even within one satellite image the water vapor concentration may vary from location to location, which makes it an extremely difficult factor to correct for. The absorption bands in the NIR region are known as the water vapor absorption bands, in the VNIR range centered at approximately 0.94, 1.14, 1.38, and 1.88 \( \mu \)m.

Ozone (O\(_3\)), strongly absorbs UV radiation and causes a shortwave cutoff of the atmospheric transmission below 0.3 \( \mu \)m. Ozone is mostly concentrated at altitudes between 20 and 50 km and its distribution is also highly variable. The total column ozone may vary from 100 to 500 Dobson units with season and type of weather. The amount of ozone is expressed in Dobson units, where 100 Dobson units is equivalent to a 1 mm layer of ozone at sea-level pressure at a temperature of 0°C.

Oxygen (O\(_2\)), which absorbs at 0.76 \( \mu \)m, and a number of other minor constituents, “trace gases”, such as methane (CH\(_4\)) and nitrous oxide (N\(_2\)O), also have minor effects on the absorptive properties of the atmosphere.

Obviously, it does not make much sense to build an Earth observation sensor for wavelengths that are
absorbed by the atmosphere. Most sensors operate in the spectral regions where the atmospheric transmission is high. These regions are called atmospheric windows. Luckily, for humans, the visible part of the spectrum falls within such an atmospheric window. We would not see very much otherwise. There are a number of windows in the NIR and MWIR regions, and the TIR region falls within one window. Then there is darkness until we enter the microwave range, where there are a number of windows again. The atmospheric windows clearly determine the spectral band placing of the Earth observation satellites (see Figure 3).

Major atmospheric windows, where atmospheric absorption is low, are as follows:

- 0.3–1.3 μm VNIR
- 1.5–1.8 μm SWIR
- 2.0–2.5 μm MWIR
- 3.5–4.1 μm MWIR
- 7.0–15.0 μm TIR
- 1 mm–1 m (microwave).

Some satellites measuring properties of the atmosphere may look at the absorption bands of the atmosphere rather than through the atmospheric windows. For instance, the spectral range around 6–7 μm is sometimes called the water vapor band (WV) as it gives a measure of the amount of water vapor in the atmosphere. It should be noted, however, that there are many water vapor absorption bands, especially in the VNIR range.

The amount of absorption by the atmosphere can be expressed by an exponential relationship with the optical depth (Equation 12):

\[ \alpha \sim e^{-\text{depth}} \] (12)

3.1.5.2 Particulate Scattering Particulates are atmospheric dust particles, called aerosols, with diameters between 0.1 and 10 μm. Particles tend to scatter radiation in all directions, depending on the size of the particle and the wavelength of the radiation. Three types of scatter models are used for particles of sizes smaller than the wavelength, equal to the wavelength, and larger than the wavelength.

Rayleigh scattering is the scattering by particles small in size compared with the wavelength being scattered. It is dominant at elevations of 9–10 km above the surface. Roughly, the scattering is inversely proportional to \( \lambda^4 \). For the visible part of the spectrum, this means that the blue light is scattered roughly 10 times as much as the red light. A blue sky is a manifestation of Rayleigh scattering. In the absence of scattering, the sky would be black.

Another type of scatter is Mie scatter, which exists when the size of atmospheric particles more or less equals the wavelength. It is a low atmosphere scattering, up to 5-km height, caused by dust, pollen, smoke, and small water droplets. The effects are approximately inversely proportional to the wavelength \( \lambda \), and affect electromagnetic radiation mostly in the visible region.

The last type is the nonselective scattering in the lower atmosphere by particles much larger than the incident wavelength. It gets its name because the effects are roughly independent of the wavelength. Nonselective scattering is the primary cause of haze. Water droplets, for example, cause such scatter. They commonly have a diameter in the range 5–100 μm and scatter all VIS, NIR and MWIR wavelengths about equally. In the VIS, equal amounts of all colors are scattered, hence fog and clouds appear white.

Scattering causes haze in imagery. It is visible as a blue haze on photographs of distant objects. In black and white photography this blue haze can be filtered by using a blue-blocking filter, which improves the haze penetration (but reduces sensitivity).

Atmospheric scattering causes the decrease in transmission in Figure 3 towards the smaller wavelengths (blue).

3.1.5.3 Atmospheric Emission The atmosphere has a temperature above 0 K and therefore radiates energy. This means that sensors looking at the thermal radiation of Earth objects also receive an unwanted dose of atmospheric radiation.

On the other hand, the emissivity together with the absorptance can be used for building a temperature profile of the atmosphere. The atmosphere has an absorptance that varies with wavelength from about 0% at 10 μm to
about 100% at 16 µm. An IR sounder with, for instance, five channels in the region from 11 to 16 µm probes the radiation of the atmosphere to different depths. Since the absorption is high at 16 µm, only the top of the atmosphere is sensed by the 16-µm channel. The 11-µm channel, however, senses the radiation from all altitudes. The other channels are somewhere in between.

3.1.5.4 Atmospheric Refraction The atmosphere also causes radiation to be bent towards the Earth, causing a minor virtual displacement of the object. For incidence angles less than about 45°, Equation (13) is applicable to satellite observations:

\[ \Delta x \approx 2.5 \sin \theta (\cos \theta)^{-4.5} \]  

where \( \Delta x \) is the observed displacement in meters and \( \theta \) is the look angle.

The displacement is about 0.5 m at a 10° look angle, 1 m at 20°, 2.5 m at 30°, 5 m at 40°, and about 8 m at 45°. This means that it was never really an important factor in the traditional RS instruments with a resolution greater than 10 m and look angles less than 30°. However, for modern high-resolution systems with extreme pointing capabilities, the displacement is of the order of a few pixels and will become apparent.

The Earth’s ionosphere and the water vapor content of the atmosphere may have a considerable effect on microwaves. At lower frequencies (150 MHz), daytime ionospheric biases can easily reach several kilometers in range.8

The atmospheric effects are difficult to model. The best model currently available is probably the Second Simulation of the Satellite Signal in the Solar Spectrum (6S),10 which is the basis of many models and programs for the correction of atmospheric effects. However, a very simple model for the energy reaching the sensor sufficing for most applications is given by Equation (14):

\[ L_{\text{sensor}} = \rho \tau^2 L_{\text{sun}} + L_{\text{skylight}} \]  

where \( L_{\text{sun}} \) is the energy from the Sun, \( \tau \) is the transmittance of the atmosphere (which is traversed twice), and \( L_{\text{skylight}} \) is the ambient light caused by scattering. The reflectance \( \rho \) of the object is the parameter in which we are interested. This can be approximated by Equation (15):

\[ L_{\text{sensor}} = a \rho + b \]  

The factors \( a \) and \( b \) can be determined from known objects present in the image. The approximation gives us a direct relationship between the values measured by the RS instrument and the physical phenomena on the ground.

3.1.6 Fluorescence

Some materials consist of molecules that absorb photons of high energy and re-emit the absorbed energy in one or more photons of lower energy. The light is transformed from a short wavelength (high energy) to a long wavelength (low energy). The term fluorescence is especially used when materials that are subjected to UV radiation start to glow with various colors. However, plants also re-emit a portion of the absorbed visible light into the red and NIR region between 0.65 and 0.75 µm. Fluorescence can be used for the identification of materials. In RS, fluorescence is applied by flashing a laser and recording the spectrum of the re-emitted light.9

3.2 Orbits

The way in which an artificial satellite “flies” is explained by the laws of Kepler. Once launched into orbit, the satellite will remain, theoretically at least, in a continuous free fall around the Earth, just like the Moon orbits the Earth, and just like the Earth itself orbits the Sun. It requires neither a pilot to fly it nor fuel, except for making minor orbit corrections. The parameters of the orbit determine to a large extent the monitoring capabilities of the sensor.

Orbit selection and sensor characteristics are closely related to the strategy required to achieve the desired results. Different types of orbits are required to achieve continuous monitoring, repetitive coverage of different periodicities, global mapping, or selective imaging. Most Earth-orbiting RS satellites use circular orbits. Planetary orbiters usually have elliptical orbits, which is less taxing on the spacecraft orbital propulsion system and combines some of the benefits of high and low orbits, thus allowing a broader flexibility to achieve multiple scientific objectives.7

Although Newton’s universal law of gravitation and Einstein’s field theory of gravity apply to satellite orbits, they can best be visualized and explained by using Kepler’s laws of planetary motion. Kepler’s laws can be applied directly to satellites orbiting the Earth, and explain the properties of the typical orbits used in RS.

3.2.1 Kepler’s Laws

Kepler’s laws of planetary motion were derived by the German astronomer Johannes Kepler, whose analysis of the observations of the 16th century Danish astronomer Tycho Brahe enabled him to announce his first two laws in 1609 in his publication “Astronomia Nova” (“New Astronomy”) and a third law a decade later, in 1619, in his “Harmonice Mundi” (“Harmony of the World”).

Brahe’s observations were remarkable because of their accuracy. He performed his minute observations without
the help of telescopes, as these were only to be invented in the early 17th century by Galileo! Kepler went on to provide the beginning of a theory of the telescope in his *Dioptrice*, published in 1611.

It is interesting that Kepler derived all three of these laws by dead reckoning: he did not have calculus available to assist him (it had not been invented then).

He began to think of planets as moving in ellipses when his data from the orbit of Mars showed that it did not follow the path of a circle, which is what everyone assumed at the time.

It is interesting that, should Kepler have been studying another planet, he would not have noticed any discrepancy between its true and predicted (circular) orbit. Mars is the only planet at the right distance from Earth and with an eccentricity large enough so that its orbit could be distinguished from a circle with the equipment available at the time.

Kepler’s three empirical laws of planetary motion can be stated as follows:

1. Each planet moves in an ellipse with the Sun at one focus point (orbits are ellipses) (see Figure 4).
2. A line connecting the planet to the Sun sweeps out equal areas in equal times (law of equal areas) (see Figure 5).
3. The squares of the periods $T$ of the planets are directly proportional to the cube of their mean distances $A$ from the Sun; $T^2/A^3$ is a constant (the harmonic law).

![Figure 4](image1.png)

*Figure 4* Kepler’s first law applied to satellites orbiting Earth; the satellite moves in an ellipse that has the Earth in one of the focus points.

![Figure 5](image2.png)

*Figure 5* Kepler’s second law applied to satellites orbiting Earth; the satellite has a higher velocity near to Earth.

Knowledge of these laws, especially the second (the law of equal areas), proved crucial to Isaac Newton in 1684–85. He then formulated his famous law of universal gravitation between the Earth and the Moon, and between the Sun and the planets, postulated by him to have validity for all objects anywhere in the Universe. Newton showed that the motion of bodies subject to central gravitational force need not always follow the elliptical orbits specified by the first law of Kepler, but can take paths defined by other, open conic curves. The motions can also be in parabolic or hyperbolic orbits, depending on the total energy of the body. Thus, an object of sufficient energy, e.g. a comet, can enter the solar system and leave again without returning.

The third law can be recognized in Equation (16) for calculating the orbital period of a certain satellite as function of its height:$^{(7)}$

$$T = 2\pi \frac{r^3}{gR^2}$$

where $g = 9.81 \text{ m s}^{-2}$, $R = 6380 \text{ km}$, and $r$ is the orbit radius.

It can be noted that Newton used his new vector calculus and laws of motion and gravitation to show that Kepler was right. One day in 1689 he came up to his friend, Edmund Halley, and casually mentioned to him that he had proved that, with a $1/r^2$ force law like gravity, planets orbit the Sun in the shapes of conic sections. This undoubtedly took Halley aback, as Newton had just revealed to him the nature of the Universe (at least the Universe as it was known then). Halley then pressed Newton to publish his findings, but Newton realised that he had forgotten the proof. After struggling to remember how he had proved the theorem, he published his work and it later appeared in full form in his *Principia*. Later, Halley examined the orbits of comets and, armed with Newton’s new understanding of the effects of gravity, computed the orbit of Halley’s comet. He predicted that it orbits the Sun once every 76 years, and named the date of the next passage. Unfortunately, he died before that year, but astronomers saw the comet come just when he said it would. For that, the comet received his name: Halley’s comet.

The usefulness of Kepler’s laws extends to the motions of natural and artificial satellites in addition to unpowered spacecraft in the orbit of planets.

As formulated by Kepler, the laws do not take into account gravitational interactions (as perturbing effects) of the various planets with each other, or of the Moon and the Sun with artificial satellites. The general problem of accurately predicting the motions of more than two bodies under their mutual attractions is complicated; analytical solutions of the three-body problem are unobtainable except for some special cases.
The physical principles of orbits are treated extensively by Rees.\(^{(9)}\)

### 3.2.2 Orbital Models

Basically, orbital models are used for two things:

1. To be able to calculate the exact location of the satellite with respect to the Earth. The position of the satellite is used for determining the exact location of each scanned pixel on Earth.
2. To know when the satellite will pass overhead and will take images of the area of interest.

Of course, point 1 is the most difficult, because it needs high accuracy. The results are used to perform geometric corrections on the satellite images. There are many programs available that are useful for predicting when the satellite will pass overhead.

Many orbital models exist, even though they all use the same theory of orbital motion. The differences are in the integration techniques used and the perturbations of the orbits that are accounted for. Each model requires its own particular set of orbital elements. Simple conversions between element sets, even though they may look similar, will lead to inaccuracy! Most orbital element sets will have a close resemblance to the Keplerian elements discussed below.

Images acquired by RS are subject to different distortions due to the Earth’s curvature and rotation, the spacecraft’s speed, altitude and attitude, the scan skew, and the projection of a spherical surface on a flat image. These distortions, if not properly accounted for, will prevent meaningful comparison among images, particularly in sequential image analysis or multisatellite data studies. Therefore, the need for image referencing, i.e. identifying the geographic coordinates corresponding to an image pixel or locating a pixel corresponding to given geographic coordinates, is inevitable in many satellite data studies.

In order to be able to establish the exact location of a pixel of a digital satellite image, a number of things must be known. First, of course, we must know what we are looking at; we must have a model of the Earth itself. Second, the characteristics of the imaging sensor must be known. Last, we must know the exact position, velocity, and attitude of the satellite at the moment of imaging.

The precision obtained depends on, amongst other things, the particular model of the Earth used. Most of the time this will be a nonspherical geoid model. The Earth models are beyond the scope of this article and will not be discussed here.

The geometric characteristics of commonly used sensors will be discussed elsewhere. This section will tackle the problem of the position of the satellite.

### 3.2.3 Often Used Orbital Models

This section discusses the most commonly used orbital models, the SGP, SGP4, SDP4, SGP8, and SDP8 models, as they were adapted by the North American Aerospace Defense Command (NORAD), which is the NASA-related organization responsible for tracking all satellites. The NORAD regularly issues updated orbital element sets. These sets contain the so-called two-line elements (TLE) for each satellite (see the next section).

The models are analytical, which means that the result can be calculated without having to perform numerical integration. This means that the calculations for determining the position of a satellite can be performed within a limited amount of time.

Five mathematical models for the prediction of satellite position and velocity are available. The first of these, SGP, developed in 1966, is used for near-Earth satellites. This model uses a simple gravitational model and it takes the drag effect on mean motion as linear with time.

The second model, SGP4, was developed in 1970 and is used for near-Earth satellites. This model was obtained by simplification of the more extensive analytical theory developed in 1969, which uses a more advanced gravitational model and a power density function for its atmospheric model.

The next model, SDP4, is an extension of SGP4 to be used for deep-space satellites. The deep-space equations were developed in 1979 and model the gravitational effects of the Moon and the Sun in addition to certain sectoral and tesseral Earth harmonics which are of particular importance for half-day and one-day period orbits.

The SGP8 model of 1980 is used for near-Earth satellites and is obtained by simplification of an extensive analytical theory, which uses the same atmospheric models as SGP4, but integrates the differential equations in a very different way.

Finally, SDP8 model is an extension of SGP8 to be used for deep-space satellites. The deep-space effects are modeled in SDP8 with the same equations as used in SDP4.

NORAD classifies all space objects as near-Earth (period less than 225 min) or deep-space (period greater than 225 min). The value of the mean motion can be used to determine whether the satellite is near-Earth or in deep space.

All this does not mean that there are no other models in use. Different models may be used for different requirements of the final result. If the result does not require high accuracy, then a simpler model than the SGP4 model could be used. If high accuracy is required for just one specific satellite, then a specific model might be used for that orbit. For instance, for the National Oceanic and Atmospheric Administration (NOAA) polar orbiting satellites the following models are known to be used (D’Souza et al.\(^{(11)}\) 153–193).
Table 3  Example of a NORAD TLE set, with its meaning listed below

1. circular model
2. elliptical model
3. Brouwer–Lyddane model
4. SGP4 model
5. Kloster model.

Furthermore, the NOAA uses its own specific orbital element set for the NOAA polar orbiting satellites, the so-called TBUS part IV elements.

3.2.4 Orbital Elements Sets

Satellite orbital elements are numbers that tell us the orbit of each satellite. The orbital elements are the parameters that drive the orbital model.

3.2.4.1 The Keplerian Elements

Seven different numbers are needed to describe accurately an orbit in space and time. Although many different sets of numbers will do (including position and velocity at a given time), there is a standard set called the Keplerian elements that are most used and most useful.

- **Epoch.** The time when the elements were made.
- **Inclination.** The angle between the orbital plane and the equatorial plane.
- **Right Ascension of Ascending Node.** The right ascension of ascending node (RAAN) is the angle between the ascending node, where the orbit crosses the equator going south to north, and the point of Ares, the reference point for the right ascension.
- **Argument of Perigee.** The angle between the perigee and ascending node, or between the major axis and the line of nodes.
- **Eccentricity.** A parameter that determines how squashed an ellipse is. Also, the ratio between the center-to-focus distance and the semimajor axis.

**Mean Motion.** The average rotation rate of the satellite.

**Mean Anomaly.** The position of the satellite in the orbit at the epoch, measured in an angle of an equivalent circular orbit moving at constant rate.

An example of a NORAD TLE is given in Table 3.

3.2.5 Perturbations

If orbital motion were that of an ideal two-body system, then the orbital elements would remain constant in time except for the mean anomaly, which would vary linearly in time. In reality, a number of perturbations slowly cause the orbit to change:

1. The Earth is not a perfect sphere, and the gravitational field of the Earth is irregular owing to inhomogeneities.
2. The additional pull of the Moon, the Sun, and the planets.
3. The solar wind.
4. The atmospheric drag and lift.
5. The Earth’s magnetic field.

The mean orbital elements of a near-Earth satellite exhibit the following effects:

1. Semimajor axis and eccentricity vary approximately linearly with time owing to atmospheric drag.
2. Inclination remains constant.
3. Argument of perigee and RAAN vary linearly with time owing to the Earth’s oblateness, and they have a small quadratic variation with time owing to the indirect effect of the changing semimajor axis.
4. Mean anomaly has an additional linear variation with time due to the Earth’s oblateness and an
additional small quadratic variation due to the changing semimajor axis.

Although it may seem that all these effects are highly undesirable, one is actually used for creating a special type of orbit that most RS satellites use. The linear change with time of the RAAN means that the orbit is slowly rotating around the Earth’s axis. This rotation is called precession, and is comparable to the slow wobble of a spinning top. Where the gravitation tries to overturn the top, because of the spinning, it actually starts to precess. More or less the same happens with satellite orbits. Because of its oblateness, the Earth has more mass on the equators and gravity tries to decrease the inclination, but, because the satellite is spinning in its orbit, the orbit precesses instead. If the parameters of the orbit are carefully chosen, the orbit can be designed in such a way that the period of precession exactly matches the 1-year orbital period of the Earth around the Sun. This means that the orbit can be chosen in such a way that the satellite always records images at the same local solar time, all year long. Such an orbit, called a sun-synchronous orbit, would not be possible without precession. The height of the orbit and its inclination are the most important factors to determine the precession period.

3.2.6 Atmospheric Drag

Usually the drag of the atmosphere will be the most important factor for changes in the satellite’s orbit. Most of the error, however, will be an error in the along-track direction of the orbit. This means that the errors in the satellite position will mostly look like a timing error; it will not pass overhead at the exact predicted time.

Bear in mind, however, that a timing error of 1 s does not look so dramatic, but in fact the satellite travels through space at a velocity of about 7 km s\(^{-1}\). A timing error of 1 s means an error in location of 7 km! Compared with the pixel size of the Landsat Thematic Mapper (TM) sensor of 30 m, this already means a location error of 250 pixels on the ground!

Most models add the following “element” to the Keplerian elements.

**Drag.** The drag orbital element simply tells us the rate at which mean motion is changing owing to drag or other related effects. Precisely, drag is half of the first time derivative of mean motion.

3.2.7 Typical Satellite Orbits

As may be clear from the previous section, although all orbits are ellipses, many choices remain for the orbital parameters, making many different orbits possible. Still, most satellites are placed in orbits with specific characteristics. Each orbit has its own particular advantages and disadvantages. The most commonly used orbits will be discussed here.

**3.2.7.1 Circular Orbit** Orbits are ellipses, and yet most satellites are in orbits that are almost a perfect circle. EO satellites are designed to fulfill one specific task, and a change in altitude would cause an undesired change in scale of the images.

On planetary missions often a highly elliptical orbit is used, because the solitary spacecraft has to fulfill a large diversity of scientific objectives. The lowest point in the orbit yields detailed images of the surface, while the highest point offers a vantage point on the planet. Only by using an elliptical orbit can a three-dimensional view of the magnetosphere be constructed.

*Advantage of a circular orbit.*

- Stable, no change of scale in the images.

*Advantages of an elliptical orbit.*

- Offers detail of the surface and a synoptic view on the planet.
- Needed for studying the magnetosphere.

**3.2.7.2 Low Earth Orbit** A low Earth orbit (LEO) is an orbit near the top of the atmosphere (150–300 km high) with a period of about 90 min.

*Advantages.*

- These orbits are the easiest to get satellites into. All other orbits require more energy and rocket fuel and thus larger and more expensive rockets.
- These orbits are “closest” to the Earth, so the sensor does not have to be very sophisticated in order to achieve high resolution.
- For active systems like SAR, a LEO requires the least power.

*Disadvantages.*

- These orbits are closest to the atmosphere and will suffer most from drag. This means that these satellites must often correct the orbit, otherwise they will spiral towards the Earth fairly rapidly and burn in the atmosphere. This is especially true in the years with high solar activity when the atmosphere swells owing to the solar wind and increased solar radiation.
• In such a low orbit the satellite views only that portion of the Earth’s surface above the horizon, which is about 3% of the total surface.

These orbits are perfect for short-time missions of the order of weeks and months. Most spy satellites during the Cold War used such low orbits. More recently, the Space Shuttle is designed specifically for using low orbits.

3.2.7.3 Near-earth Orbit  
Orbits between 300 km high and roughly twice the Earth’s radius, 6400 km high. Most satellites are in a near-Earth orbit (NEO), high enough to experience little drag by the atmosphere, but low enough to view much detail of the Earth’s surface.

**Advantage.**

• Less drag.

**Disadvantage.**

• The sensor has to be more advanced in order to achieve the same resolution as in a LEO.

3.2.7.4 Prograde  
Orbits having an inclination angle between 0° and 90° are the eastward-launched orbits. It is cheaper to launch a rocket in an eastern direction, because it already has the speed of the rotational speed of the Earth, which can be as much as 0.5 km s\(^{-1}\) on the equator. A major disadvantage of this type of orbit is that the precession rotates in the wrong direction: instead of rotating with the Earth, the satellite precesses against the Earth, making a Sun-synchronous orbit impossible.

**Advantage.**

• Requires less fuel than a retrograde orbit.

**Disadvantage.**

• Cannot be used for a Sun-synchronous orbit.

3.2.7.5 Retrograde  
Orbits with angles between 90° and 180° are the westward-launched orbits. The latter are the so-called retrograde orbits.

**Advantage.**

• Makes Sun-synchronous orbit possible. All Sun-synchronous orbits are retrograde orbits.

**Disadvantage.**

• Retrograde orbits require more fuel as the rocket has to compensate for the Earth’s rotation, which may be as much as 0.5 km s\(^{-1}\), which is considerable compared with the final orbiting speed of about 7.9 km s\(^{-1}\).

3.2.7.6 Polar or Near-polar  
If a satellite were to be launched with an inclination angle of 0° then it would orbit the Earth over the equator. In a low orbit this would mean that it could only see parts of the Earth along the equator. In order to see more of the Earth, the orbit would have to have a certain inclination. If the inclination were 60° then the satellite would fly over the Earth between latitude 60° south and 60° north; it would never see parts of the Earth at latitudes higher than 60°!

Ideally, for a satellite to see the entire Earth, it would have an inclination between 80 and 100°. Such an orbit, over the poles, is called polar or near-polar. A satellite in this orbit is sometimes called a polar orbiter.

**Advantage.**

• Eventually covers the entire Earth, also offering a good view of the poles.

3.2.7.7 Sun-synchronous  
An orbit chosen in such a way that the satellite always passes overhead at the same local solar time is called Sun-synchronous. Most orbits cross the equator, going from north to south (descending), at mid-morning, so images are taken when the Sun angle is low and the resultant shadows reveal terrain relief. Note that night-time images can be recorded during the ascending phase of the orbit.

**Advantage.**

• The Sun’s position and lighting conditions for all the images are always the same (within certain limits). This makes it very easy to compare images from different dates.

**Disadvantages.**

• Varying Sun angles might help geologists to reveal subtle structural details that are not always visible at constant solar angles.

• It requires a retrograde orbit.

• In order to keep it Sun-synchronous, the subtle relationship between the orbital parameters must be preserved, which makes it more difficult to maintain.

Understanding the dynamics of the Sun-synchronous orbit is not so trivial. A constant orbit could never be Sun-synchronous. An orbit can only be Sun-synchronous if it precesses around the Earth at the same rotational speed (in degrees) as the Earth orbits around the Sun. In other words, the orbital plane rotates around the Earth at an angular rate of about 1° per day, in order to match exactly the angular rotation of the Earth around the Sun of 360° during the 365 days of 1 year (see Figure 6).
3.2.7.8 Geo-synchronous

A geo-synchronous orbit has an orbital period that is an integer multiple or submultiple of the Earth’s rotation rate, resulting in a repeating ground track. Very often the term geo-synchronous is confused with the term geo-stationary (see the next section). Every geo-stationary orbit (GEO) is geo-synchronous, but not every geo-synchronous orbit is geo-stationary. In fact, most RS satellites have a repeating ground track, but are not geo-stationary. The footprint of the satellite’s orbit on Earth, its “path”, is kept fixed (within certain limits), and maps can be obtained outlining these paths on the Earth’s surface. Images of an entire path are chopp ed up at regular intervals, the “rows”. Thus each scene or “picture” can be indicated by the “path and row” of its “scene center”. For instance, the path and row grid of the Landsat satellites is called the World Reference System (WRS). The regular return of the satellite on a certain path is called the repeat cycle. The repeat cycle together with the pointing capability of the sensor determine how much time will pass before a sensor can generate another image of the same location. This is called the revisit time. Landsat 5 has a repeat cycle of 16 days and its sensor is not steerable, which means it has a revisit time of 16 days. The SPOT 4 satellite has a repeat cycle of 26 days, but its sensors can be directed to the left and the right, and thus achieve a revisit time of 4–6 days depending on the latitude of the scene.

Owing to perturbations, a satellite may slowly drift from its fixed path pattern. Small variations may be permitted before corrective action is taken by the mission control center.

Most RS satellites take daytime images during the descending phase of the orbit, which means that nighttime images can be recorded during the ascending phase of the orbit. Landsat, for instance, records thermal IR TM (a sensor on-board Landsat) images in the ascending phase. Radar systems record their images on only one side of the track. The possibility of also taking images at night (which for an active system does not really matter!) means that objects can be viewed from both sides. This opens up the possibility of doing stereoscopy with radar images. The science of measuring height and positions in stereo pair radar images is referred to as radargrammetry.

**Advantage.**

- The satellite follows a fixed pattern on the Earth, which makes reference of scenes by a path and row grid easy.

**Disadvantage.**

- As satellites slowly drift from their orbit, a geo-synchronous satellite must be corrected occasionally to keep it on the track of its predetermined paths.

3.2.7.9 Geo-stationary Orbit

Arthur C. Clarke was the first to conceive the idea of stationary satellites, in
From their orbits 35 680 km above the equator, GEO satellites match the Earth’s rotational period of about 24 h and thus remain stationary in relation to a selected point on the Earth’s surface. They view about 45% of the globe, compared with the 3% of a spacecraft in a 320-km orbit. The view from GEO is “Olympian” compared with the “worm’s-eye” view of ground-based observers.

Advantages.

- Continuous observations. A picture of a hemisphere’s weather can be obtained every 15–30 min on an operational basis, and even every minute whenever necessary, e.g. in severe weather.
- From its vantage point in the sky, it views almost half of the globe at the same time.
- The satellite is always in view, which allows a real-time downlink for data.
- The position of the satellite, in fact, is more or less fixed (within 0.5° or so) in the sky, so it is very easy to point a fixed dish at it. Data transmission is easy, because the dish does not have to follow the satellite.

Disadvantages.

- Because of its height it requires a heavy rocket, which makes it the most expensive orbit to get into.
- Because of the distance to the Earth, the resolution of RS instruments from this orbit is low.
- Because of its position in the equatorial plane, it offers only an oblique view on the poles, which degrades the resolution at higher latitudes.

Modern meteorological weather satellite systems use a combined system of geo-stationary satellites and polar orbiters. The geo-stationary satellites offer a continuous view, whereas the polar orbiters offer a better resolution (see Figure 8).

3.2.8 Other Orbits

As pointed out, the laws of Kepler are fine for a two-body problem, Sun–planet or Earth–satellite, but are useless for three or more bodies. For a satellite circling two massive bodies, it appears that there are five points where the pull of gravity of these two bodies is at equilibrium. These points are called Lagrangian or libration points L1–L5. At these points a satellite can be positioned at zero velocity with respect to both bodies. Three of these points are on the line passing through the centers of mass of the two massive bodies. L3 is beyond the most massive body, L2 beyond the least massive body, and L1 between the bodies. The other points L4 and L5 are located at equal distances, in an equilateral triangle, from the two main components in the orbit of the least massive object.

L4 and L5 are stable points, and a satellite positioned at one of these points, even after small perturbations, will always remain at this point. A satellite located at L1, L2, or L3 is unstable, and will eventually wander off if slightly disturbed. A thruster engine must be provided for small orbit corrections.

The L4 and L5 points of the Sun–Jupiter system are actually occupied by a number of asteroids referred to as the Trojans. The first Trojan, Achilles, was discovered in 1906 and now more than 50 are known.

The L1 point has already been used by a number of solar observation satellites, studying the Sun and the solar wind outside the Earth’s magnetic field, for instance the Solar and Heliospheric Observatory (SOHO). In 2000 the Triana satellite will be placed at the Earth–Sun L1 point, about $1.5 \times 10^6$ km from the Earth, where it can maintain its fixed position between the Sun and the Earth and continuously see the full sunlit disk of the Earth. In the far future the L4 or L5 point of the Earth and Moon may be used for a space station.

4 REMOTE SENSORS

The terms instrument, sensor, and detector are not strictly defined, and are usually freely interchanged, although by detector is usually meant the energy-measuring element. By sensor we generally mean the detector plus optics. The term instrument mostly refers to the entire module, containing the sensor and electronics, as it is attached to the satellite platform. The platform, in turn, contains all sensor instruments plus additional instruments for maintaining orbit and attitude, communication, telemetry and command link, and more.

Remote sensors can be classified in many ways. The classification followed here first distinguishes passive sensors from active sensors, then classifies them by increasing complexity.
MS sensors use devices that scan the Earth and take measurements point by point rather than taking one picture in one shot, as in aerial photography. Either the point measurements are collected in an electromechanical way (with a moving mirror) or fully electronically (with no moving parts). This has the obvious disadvantage that the measurements are taken at slightly different times and may be difficult to relate to each other. However, MS sensors have some major advantages over photography:

- Photographic systems are limited to the spectral range 0.3–0.9 µm. MS systems have an extended range from 0.3 to roughly 14 µm. This range is usually referred to as the optical domain, which is the spectral range that can be manipulated by using optics (lenses). Some sensors may even operate in the microwave region of the electromagnetic spectrum, which roughly spans the wavelengths between 1 cm and 1 m; these waves can only be handled with electromagnetic fields.
- MS systems can record images in many very narrow spectral bands, which is referred to as imaging spectrometry.
- Photographic data are difficult to calibrate because of the photochemical processing involved. MS data are as stable as the electronics involved, which are much more stable than the photochemical processing. Calibration tries to reverse the measurement values back to the physical units of the observed phenomena.
- Electronic detectors also allow a much larger dynamic range, which is the operational range between the minimum and the maximum input that the detector can handle.
- Photographic systems require transportation of film to and from the platform. MS data allow electronic transmission to ground receiving stations, and can even offer near real-time viewing of the ground scene.
- MS data are readily available in digital form and do not need an additional scanning step for further electronic processing.

### 4.1 Passive Radiometry

Most RS systems use the indirect solar energy reflected by the object as their prime source. The system does not actively probe the object with some form of energy, hence the name “passive sensors”. Another source of energy may be radiation emitted by the objects themselves. All objects having a temperature above 0 K emit energy. At 300 K, the top of the blackbody curve is located in the middle of the TIR region of the spectrum. Objects may also emit other forms of energy. Well known are the images of city lights from space taken by the Defense Meteorological Satellite Program (DMSP) satellites. The same satellite has also taken images from the Aurora Polaris.

A detector is a device that transduces incident energy into a signal. Typically, a detector needs a certain amount of time to build up a signal. This time is called the integration time, or dwell time. The signal from the detector will be proportional to the aperture of the detector and the integration time. Preferably, there is a linear relationship between the energy falling on and the signal coming from the detector.

Detectors for the IR range must be cooled in order to reduce stray radiation from the sensor itself to be detected.

#### 4.1.1 Aerial Photography

Photography has long been the only means of recording images by RS. It is still being used intensively on-board aircraft, and there are a number of spaceborne cameras. For instance, the Russian KVR-1000 camera flown on-board a Cosmos satellite delivers images for Space Information – 2 m resolution (SPIN-2). The images are available on the Internet.\

Only a few aspects of photography will be treated here. Other sources such as the *Manual of Remote Sensing* and Lillesand are excellent sources for further reading.

The following elements can be distinguished in a camera:

- the camera body and film magazine
- the optical system, comprised of a number of lenses
- the film
- the diaphragm
- the shutter
- the filter
- the exposure control system
- an auxiliary data system.

A camera projects the scene on to a film in a so-called central projection. A displacement in height of the object will cause a displacement in the image plane. Although this is bad for topographic mapping, because objects are not imaged at the expected location in the image, these small displacements can actually be used to measure the height of the object. Using two or more images taken from different positions does this, and is called stereoscopy. Photogrammetry is the science of measuring positions and heights in aerial photographs. Distortions in the optical system (aberrations) and stretch of the film determine the geometric accuracy of the image.

The grain size of the film, the quality of the optics, the aperture, and other factors determine the spatial resolution of a camera system. The optical quality of a photographic system is usually determined by constructing a modulation transfer function (MTF).
MTF plots the relative modulation depth of the response of a square-wave test pattern offered to the camera. However, although the MTF gives a good indication of the resolution of the system, one should remember that the final resolution of a photograph depends on many factors.

The spectral characteristics of a photographic system are determined by the sensitivity of the film and the filters used. Normal emulsion is sensitive only to blue light. The film can be sensitized to have an extended spectral sensitivity into the green (orthochromatic emulsion), red (panchromatic (PAN) emulsion) and IR (IR-sensitive emulsion) regions. Colored-glass or coated-glass filters can be used to limit the sensitivity to a certain spectral range.

**Advantages.**

- large image format
- high information density (one aerial photograph has an equivalent information content of about 600 Mb)
- high geometric integrity.

**Disadvantages.**

- transmission of film
- radiometry is difficult to control
- limited spectral coverage in the VNIR range
- analog output.

**4.1.2 Cathode-ray Tubes**

Although the early systems carried the equivalent of television tubes (TIROS-1, Landsat 1), these are hardly used now because of the advantages of solid-state detector systems. Sometimes modern video equipment is carried on-board aircraft for recording the state of the environment.

**4.1.3 Solid-state Detectors**

Electro-optical systems as radiation detectors are transducers that transform electromagnetic radiation into electrons or other detectable signals to convey the measurement information of the viewed scene. The description of types of detector materials, such as photoconductors, photodiodes, and charge-coupled devices (CCD) can be found, for instance, in the Manual of Remote Sensing. Here, we will mention only a selection of general properties of detectors.

The whole range of input intensity values, between a maximum and a minimum signal that a detector can handle, is called the dynamic range. The ratio between a change in output value as a result of the changing input value is referred to as sensitivity, gain factor, or gamma. An ideal detector has the same sensitivity over the dynamic range, i.e. the gain factor is independent of the input level. Such a detector is said to be linear. The output of a digital detector is quantized into a limited number of levels by an analog-to-digital converter (ADC). The higher the number of levels in the dynamic range, the more intensity values in the input can be distinguished. The smallest input level that can still be distinguished in input is called the radiometric resolution; more levels improve the radiometric resolution. Usually, the smallest level that can be resolved in input is determined by the noise in the system. The more noise in the detector system, the more the radiometric levels will become blurred and the less the radiometric resolution will be.

Each detector has a useful sensitivity in its own spectral range. The graph that plots the sensitivity of the sensor for each wavelength is called the spectral response function (SRF). A filter can be applied for narrowing the spectral range of a sensor. The position of the central wavelength of the SRF determines the spectral band of the sensor. The width of the SRF determines the spectral bandwidth. The bandwidth is usually determined by the difference of the two wavelengths where the SRF is half as high as its maximum peak value. This is called the full width at half-maximum (fwhm) value.

Preferably all the characteristics of the sensor are known, and they can be determined by calibration. Calibration is the characterization of a sensor in the spatial, spectral, and radiometric domains. The process of calibration involves standard or invariant objects, and can be done either before or after the sensor is taken into operation. Ideally, calibration makes the measurements independent of the instrument. This means that when a particular physical entity is to be measured at different times and places or with different instruments, the results should always be the same. The ultimate measurements should carry only object attributes, not sensor attributes. Unfortunately, the nature of the interactions of electromagnetic waves with the object, the atmosphere, and the sensor is highly complex, which makes it almost impossible to obtain the ideal calibration for all practical situations.

Apart from that, sensors appear to change over time, which makes frequent recalibration essential. Several internal or external sources can be used for in-flight calibration. If the sensor is sufficiently linear by nature, a dark and a bright (or cold and hot) source are sufficient to construct a new calibration curve. Still, the calibration method itself may degrade over time. A constant external source may not be so constant after all. A diffuser, used to soften the light of the Sun directed on to the sensor for calibration purposes, may degrade over time, necessitating a second, less frequently used diffuser. For instance, the Medium Resolution Imaging Spectrometer (MERIS) sensor on-board the environmental satellite (Envisat) will apply the latter technique. Of course, this
calibration of the calibrator can be carried out with endless recursion. The fact is that the calibration and validation of remote sensors are attracting more and more attention and some organizations execute regular under-flights for comparison of airborne and spaceborne data.

The calibration data can then be used to determine the physical properties of the object under study (radiance, reflectance, temperature, etc.) from the digital number (DN) values.

4.1.4 The Sounder

The simplest sensor is composed of one straight-downward looking detector. Such a detector would take measurements of small ground areas of the Earth. During its orbit the satellite can measure the energy from a number of points along its path on the Earth. Each measurement is taken at discrete distances on the Earth, and is called a sample. The distance between the samples is called the sample distance. The radius of the area covered by one such measurement is called the resolution. The DN expresses the value of the measurement and is called the DN value, the radiometric value, or simply the “value”.

The sample distance and the resolution together determine how much spatial detail can be observed in the recorded measurements. The sensor could be instructed to take more than one sample within the resolution of the detector. However, this would not make any sense, as the detector would measure most of the ground area of the previous sample! In this case, the detail that one can observe is limited by the resolution. On the other hand, a sensor built with a resolution much smaller than the sample distance would not make much sense either, as the sample distance limits the amount of detail in this case. Besides, the sensor would not even measure much of the total area at all! This is exactly the reason why most sensors are designed in such a way that the sample distance more or less equals the resolution. Hence sample distance and resolution are often freely interchanged. The problem with this is that this leads to thorough confusion (even among RS experts!) about the very different natures of sampling and resolution. Sampling, when and where the next measurement is taken, is determined by the electronics and the orbit, whereas resolution, the extent of one measurement, is determined by the angular aperture of the detector and the quality of the optics. The angular aperture is called the instantaneous field of view (IFOV).

In order to build up an image of the Earth, many measurements, or samples, must be recorded. By taking samples along the path of the satellite and combining these with sample of adjacent paths, a two-dimensional matrix of measurements can be built up. Thus, the satellite image is born.

Note: suppose the speed of a (hypothetical) satellite’s footprint on the Earth is 6 km s\(^{-1}\) and that we want to take samples every 1 km. In order to achieve the sample distance of 1 km along the track, the sensor must take six samples every second. In other words, the detector has one-sixth of a second to take one measurement. In order to achieve the sample distance of 1 km across the track, the pattern of paths of the satellite’s successive polar orbits must be spaced at 1 km at the equator. The circumference of the Earth is about 40 000 km, which means that the satellite completes about 13 orbits per day (one day contains 86 400 s; during one day the satellite travels 6 km s\(^{-1}\) \times 86 400 s, which is 518 400 km or 40 000 km per orbit around the Earth.) It takes the satellite 6670 s (40 000 km/6 km s\(^{-1}\)) to complete one orbit. During the time the satellite rotates around the Earth, the Earth itself rotates around its axis. The rotational speed of the Earth is about 1670 km h\(^{-1}\) (40 000 km/24 h) on the equator, which means that the Earth has moved 3086 km at the next equator crossing of the satellite. This in turn means that the next orbit is not adjacent to the previous orbit! We will have to wait longer for the satellite to visit adjacent paths. However, this poses a problem: as each orbit lasts more than 1 h (6670 s = 1.9 h), things might change on Earth. The Sun-angle changes, the cloud cover (CC) may change, or the phenomena under investigation may change. This is unacceptable. Another problem is that it would take 40 000 orbits (to achieve a 1-km sample distance on the equator) to acquire a global image. This would need more than 8 years! (40 000 orbits/13 orbits/day for 365 days/year = 8.4 years).

Although a sounder has the advantage that it always looks straight down, which means the measurements are independent of the height of the object, it is not a practical solution for taking high-resolution images of the Earth. An obvious solution would be to take multiple measurements across the track of the satellite. Both the scanner and the pushbroom sensor do exactly that. They can record an image in a short time, and the pattern of their paths on the Earth does not have to be so dense.

4.1.4.1 Microwave Sounders

Microwave sounders are used for measurements to map surface temperatures, subsurface structures, or atmospheric profiles of temperature, composition, and pressure as a function of altitude. Sounders use the emission of objects themselves as a source of energy. The microwave region is in the low-energy tail of the 300 K blackbody radiation curve (see paragraph 3.1.3). In this spectral region, all objects in the natural environment emit microwave radiation, albeit faintly. Because of the extremely weak magnitude, the signal is very noisy compared with that which cameras, visible or IR scanners, or radar provide. Common to all radiometer designs is the trade-off between antenna beam width and system sensitivity. Because of
the very low levels of radiation available to be passively sensed in the microwave region, a comparatively large antenna beam width is required to collect enough energy to yield a detectable signal. Consequently, passive microwave radiometers are characterized by low spatial resolution.\(^2\)

Because microwave sounders operate on the same energy curve as TIR sensors, images from sounders bear a strong resemblance to TIR images, although transmission of the top layer may unveil microwave emission from subsurface structures.

4.1.5 The Scanner

A combination of a single detector plus a rotating mirror can be arranged in such a way that the detector “beam” will sweep a straight line of the Earth across the track of the satellite at each rotation of the mirror. The forward motion of the satellite takes care of positioning the satellite above successive lines (see Figure 9). Thus the scanner is born. Because of the sweeping motion, the across-track scanner is sometimes referred to as a whiskbroom.

The aperture or opening angle determines the tiny area that the detector sees at one glance of the Earth (the ground cell), and is called the IFOV. The IFOV is constant over the entire line, and this means that the resolution degrades at increasing scan angles left and right of the satellite track. The along-track resolution decreases with \(1/\cos \theta\) and the across-track resolution decreases with \(1/\cos^2 \theta\), where \(\theta\) is the scan angle. Clearly, the fact that the scanner measures ground cells at constant angles causes geometric distortions. The curvature of the Earth causes additional distortions, especially for a large field of view (FOV).

An extreme example of this is the advanced very-high resolution radiometer (AVHRR) sensor, which has a FOV of 110\(^\circ\), where the resolution degrades from approximately 1 by 1 km at nadir to 6 by 3 km at the limb of the sensor.

The swath pattern and orbital path are designed in such a way that images of adjacent paths have a degree of lateral overlap. The amount of overlap is minimal at the equator, but the side overlap increases towards the poles.

**Advantages.**
- simple detector
- simple optics
- wide FOV capability
- extended spectral sensitivity (compared with a CCD).

**Disadvantages.**
- short dwell time
- moving parts
- lower geometric stability.

Note: consider the same (hypothetical) satellite as mentioned above, but now equipped with a scanner instead of a sounder. Again, we want to have a sample spacing of 1 km. Furthermore, suppose we want to record 2000 samples per line, which gives the sensor a swath on Earth of 2000 km (not considering distortions). The speed of the satellite of 6 km s\(^{-1}\) has not changed, because it is in the same orbit. This means that in order to achieve a line spacing of 1 km the sensor has to record six lines per second, which in turn means the detector has to record 2000 samples per second! This shows that the dwell time of the scanner has decreased dramatically by a factor of 2000 compared with the dwell time of the sounder (not considering the dead time of the rotating mirror). Obviously, there is a trade-off between the number of samples per line and the time the detector has to take one sample. A major advantage is that global coverage can be achieved within 20 orbits (40 000 km Earth radius/2000 km swath), which is less than 2 days.

The dwell time or integration time is the time needed by the detector to build up one measurement. At the expense of a much shorter dwell time, the sensor can record large swaths at the same time, and global coverage can be achieved within a reasonable time. If the dwell time becomes too short, the noise levels of the sensor increase. In order to give the detector longer dwell times, multiple detectors can work in parallel. For instance, the TM sensor of the Landsat satellite uses 16 detectors in parallel per spectral band. In addition, the TM uses an oscillating mirror rather than a rotating mirror, and sweeps the Earth in both left–right and right–left motions, which reduces the dead time of the mirror almost to zero. By these measures the TM achieves an acceptable dwell time for its detectors.
The use of parallel detectors comes at a cost. Instead of having to calibrate one detector, many detectors must be checked. Differences between the detectors are visible in the recorded images. TM images may suffer from horizontal banding caused by differences in sensitivity of its 16 detectors per band. The banding pattern will repeat itself after 16 lines (see also Figure 14). This banding is called “striping”. Also, a single detector sensor may exhibit striping, as the characteristics of the detector may be influenced by the received energy (e.g. overload). If a detector saturates on a very bright object, it may give a faulty response on the next few pixels and lines.

The ultimate step in parallelism would be to record all samples across the scan line with an individual detector. This would also remove the need for a moving mirror! Such an arrangement of an array of detectors recording all samples of a line in parallel is referred to as a pushbroom.

4.1.6 The Conical Scanner

The conical scanner also uses a rotating mirror, but in a different geometrical arrangement. The detector sweeps the ground in circles (see Figure 10). The advantage of this is that the angle of incidence is the same for all objects, and also the path through the atmosphere is a constant. A disadvantage is the extreme geometrical distortion caused by the cycloid scanning pattern. In fact, the same pattern can also be achieved by a rotating satellite, which requires no moving mirror. Many passive microwave atmospheric sounders use conical scanners. One MS system to use this principle is the MSU-SK sensor carried on-board the Russian Resurs-O1 satellites.

4.1.7 The Pushbroom

Modern pushbroom sensors use linear array CCDs (see Figure 11), which are composed of thousands of equally spaced detectors. They act as a linear camera, recording one entire line at the time. The pushbroom requires no moving parts, as opposed to the scanner, and offers better signal levels because of the increased dwell time.

Also, the geometric distortion of a pushbroom is less than that of a scanner, because the central projection of each line causes no distortions in vertical images. If the terrain is flat there is a one-to-one correspondence with the position of the object and the position of the detector. Actually, the opening angle of each detector varies with its position in the array, and is not a constant like the IFOV of the scanner. Therefore, it is incorrect to speak of the IFOV of a pushbroom.

Note: again, considering the hypothetical satellite mentioned above, by using a pushbroom, each individual detector can take as much one-sixth of a second to form one measurement of one ground cell.

Advantages.

- The pushbroom has no moving parts, which gives it a longer life expectancy.
- All elements of the pushbroom are at fixed distances from each other. This means that recorded data will not suffer from geometric distortions caused by irregular movements of the scan mirror.
- No IFOV.
- Long dwell time.

Disadvantage.

- State-of-the-art CCDs have a limited spectral sensitivity up to about 2.5 µm.
- Needs wide FOV optics.
Also with the pushbroom the parallelism comes at a cost. Although one might expect all the detectors of the linear CCD to have similar characteristics, there is a limit to the control in the production process of CCDs. Each element will have its own properties, and instead of having to calibrate one, or just a few, detectors, one may have to calibrate thousands of detectors of the linear CCD. Differences between detectors are visible in the recorded images. As opposed to the horizontal striping in scanner images, pushbroom images may suffer from vertical banding.

4.1.8 The Two-dimensional Charge-coupled Device

The two-dimensional version of the linear CCD chip can be used as a replacement of the film in a camera. The advantage of using an electronic detector over film is that the data are immediately available in digital form. The process of taking snapshots of the Earth along the orbit of the satellite is referred to as step staring. A geo-stationary satellite can apply the two-dimensional CCD as a video camera pointed at the Earth; this is referred to as fully staring. Some heat-sensitive geo-stationary missile detectors seem to apply this technique. The TRMM satellite carries a lightning imaging sensor (LIS), an optical staring imaging system to detect the rate, position, and radiant energy of lightning flashes.

4.1.9 The Imaging Spectrometer

A modern and popular design of the imaging spectrometer is the pushbroom using a dispersive element together with a two-dimensional CCD chip. One line of the Earth is projected on to a dispersive element (grating or prism), which separates the line image into a series of lines, each corresponding to a spectral band. In this way each column of the chip records the spectrum of one ground cell. Each row images each ground cell in one particular spectral band. The whole process is repeated as the platform moves one line along the track. Imaging spectrometers (or hyperspectral imagers) allow the simultaneous acquisition of images in many, contiguous, narrow bands. Traditional remote sensors have few and broad bands, whereas imaging spectrometers may have hundreds of narrow bands. They allow the recording of spectra of each ground cell much like using a spectrometer in a laboratory. One major problem of using an imaging spectrometer is the high volume of the data. Some existing airborne systems allow averaging of rows or columns on the two-dimensional CCD chip, thereby offering the possibility of exchanging spatial resolution for spectral resolution and vice versa (for instance the CASI instrument).

Some instruments are imaging spectrometers by design, but deliver only a limited number of bands from the whole range of possibilities. The advantage of this is that the band position and width can be reprogrammed at a later stage. For instance, the MERIS instrument of the Envisat satellite delivers only 15 bands, while it is actually a fully fledged imaging spectrometer. MERIS’s spectral resolution is actually very high, and it allows the bands to be reprogrammed at wavelength steps of 1.25 nm!

4.2 Active Radiometry

Unlike in airborne radar observation, where relatively simple side-looking airborne radio detection and ranging (SLAR) can be carried, spaceborne RS requires a different technique. Spaceborne radar would require an unacceptably long antenna in order to achieve the same resolutions as airborne radar. Instead, a long antenna in space is synthesized by combining signals from different positions along the orbit of the satellite. Such a radar system is called synthetic aperture radar (SAR). Building such radars demands the utmost of electronics, signal processing, electromagnetic fields, and antenna design. Also, the interpretation of radar images is difficult, because the return signal from the object can be influenced by many factors. For instance, the reflected intensity from trees is affected by the leaves, the branches, the trunk, the shape and structure of the branches, the surface below the tree, the surface roughness of the soil below, the humidity of the soil, and subsurface structures under the soil.

Radar can be used for determining the amount of vegetation on the ground, but then the other parameters, such as surface roughness and soil humidity, must be known.

Imaging radars have been flown on a number of spacecraft, including Seasat, the Japanese Earth Resources Satellite (JERS) 1, ERS 1 and 2, Radarsat 1, and the Space Shuttle. Shuttle Imaging Radar C (SIR-C) is currently the most advanced imaging SAR, capable of shooting radar images at three different microwave frequencies and multipolarization mode. With this system, up to nine different radar images can be obtained from an object simultaneously, offering an unprecedented view of the object’s composition and structure. Future plans for the Shuttle include flying a second radar system connected with a 60-m boom to the first in order to acquire, for the first time, simultaneous images for interferometric SAR.

4.2.1 Altimetry

Radars are also used in a nonimaging mode as altimeters. Altimeters use the ranging capability of radar sensors to measure the surface topographic profile, by simply emitting a pulse and measuring the time between emission
and reception. The height $h$ bears a linear relationship to the time lapse $t$ (Equation 17):

$$h = \frac{ct}{2}$$

Of course, the pulse travels at speed $c$ through space. Altimeters have been flown on a number of spacecraft, including Seasat, ERS 1 and 2, and TOPEX/Poseidon. The water height of the oceans is influenced by a number of factors. Seasat is known for the first images of the topography of the ocean floor. A dip in the ocean floor causes a dip in the water surface, because there is less gravitational pull from the Earth’s crust. The water level can vary by roughly 150 m, caused by the ocean floor topography. Knowing the mean water level of the oceans, minor variations on top of the mean level can be measured. TOPEX/Poseidon is known for measuring the ocean temperature by these changes. There appears to be a direct relationship between temperature and water height. The sea surface temperature reflects the temperature in the top few centimeters of water, and the temperature can change dramatically with depth in some cases. The sea surface measured by altimetry is related to the temperature at all depths, in addition to other parameters, such as the water salinity and ocean currents. Note that, in general, the movement of currents has a greater effect on sea level ($\pm 1$ m) than heating and/or winds ($\pm 12$ cm).

All spaceborne radar altimeters to date have been wide-beam systems, limited in accuracy by their pulse duration. Such altimeters are useful for smooth surfaces (oceans), but are ineffective over relatively high relief continental terrain. A fundamental problem in narrow-beam spaceborne radar altimetry is the physical constraint of antenna size. Again, large antennas are required for small radar footprints.

### 4.2.2 Scatterometers/Spectrometers

Scatterometers are radar sensors that provide the backscattering cross-section of the surface area illuminated by the sensor area. They are particularly useful in measuring the ocean backscatter as a means of deriving the near-surface wind vector. The strength of the radar backscatter is proportional to the amplitude of the water surface capillary and small gravity waves (Bragg scattering), which in turn is related to the wind speed and direction near the surface.

### 4.2.3 Imaging Synthetic Aperture Radar

Imaging radar data are being used in a variety of applications, including geological mapping, ocean surface observation, polar ice tracking, and vegetation monitoring. Most of these applications are still in the development stage, because our knowledge is still limited on how to extract information from radar image data and how to use the various possibilities of radar parameters, such as frequency, polarization, incidence angle, resolution, and swath width. Qualitatively, radar images can be interpreted in very much the same way as optical images. In general, one could say that radar reveals more of the structure of an object, and optical images show more of the composition.

Man-made objects usually stand out very bright in radar images, because many objects act as corner reflectors for the radar signal. Houses, bridges, and other constructions can easily be found.

#### 4.2.3.1 Speckle

The first impression of radar images is that they have a very noisy character. This noisy appearance results from the backscatter contributions of the many scattering points of the surface area, even within one ground-cell. Even though its properties do not change, the same ground-cell may look completely different from different positions (an image from exactly the same position will give exactly the same measurement). This type of “noise” is related to location rather than time. The noise is caused by the coherent scatterers and not by bad signals by the radar system, and is called speckle. The way to improve the noisy appearance of radar imagery is to take a number of images and average them. This multilook technique will reduce the speckle by the square root of the number of “looks”.

#### 4.2.3.2 Pulse-time Measurement

Actual imaging SARs use a series of pulses instead of a continuous signal. Each transmitted wave front hits the target surface at near range and sweeps across the swath to the far range. The return pulses are timed and recorded. The signals of each swath are said to be in the slant range; the objects are in ground range. The transformation of signals in the slant range to the ground range is not a trivial one and involves the incidence angle and the height of the object, and sometimes cannot be solved at all because of overlapping signals (see below), i.e. signals from different objects arriving at the same time. This problem of signals arriving at the same time is also the reason why all imaging radars are side-looking. This removes the left–right ambiguity of signals from objects at the right and the left side of the radar.

The pulse bandwidth $B$ determines the cross-track resolution (Equation 18):

$$C = \frac{c}{2B \sin \theta}$$

where $c =$ speed of light, $B =$ pulse bandwidth, and $\theta =$ incidence angle. The presence of the incidence
angle $\theta$ in the equation is the reason for varying resolution and scale across the slant-range of a radar image.

The along-track resolution $A$ of a real-aperture radar is inversely proportional to the antenna length $L$ (Equation 19):

$$A = \frac{h\lambda}{L \cos \theta} \quad (19)$$

where $h =$ height above ground, $\lambda =$ wavelength, $L =$ antenna length, and $\theta =$ incidence angle.\(^8\)

However, interestingly enough, theoretically the along-track resolution $A$ of a SAR is proportional to the antenna length $L$ (Equation 20):

$$A = \frac{L}{2} \quad (20)$$

In theory, the resolution for a 1-m antenna would be 0.5 m, independent of the height! However, since short antennas have stability problems, radar design is replete with tradeoffs among operating range, resolution, wavelength, antenna size, and overall system complexity.\(^2\)

4.2.3.3 Synthetic Aperture Radar Polarimetry The roughness and composition of materials may cause a change in the polarization angle of the return signal with respect to the incidence angle. This change in polarization thus offers yet another possibility to characterize materials on the surface of the Earth. Current operational systems typically only record the like-polarization modes, either transmitting horizontally polarized signals and receiving horizontally polarized signals (HH polarization), or transmitting vertically polarized signals and receiving vertically polarized signals (VV polarization). However, experimental systems have already proven the usefulness of the other polarization modes. Future radar satellites will also be capable of recording the cross-polarization modes, horizontal transmission–vertical reception (HV), and vertical transmission–horizontal reception (VH).

4.2.3.4 Synthetic Aperture Radar Interferometry Recently radar RS has proven very valuable with the advent of interferometry. The use of SAR as an interferometer is rather new owing to the stringent requirements as regards the stability of the satellite orbit. INSAR offers the possibility to map the Earth’s land and ice topography and to measure small displacements over large temporal and spatial scales with subcentimeter accuracy. INSAR makes use mainly of the phase measurements in two or more SAR signals of the same scene, acquired at two different moments or at two slightly different locations. By interference of the two images, very small slant-range changes can be related to topography and surface deformations. INSAR thus has the potential for mapping centimeter-scale ground displacements over a region of many tens of kilometers in size at a resolution of a few meters, making it one of the most promising space geodetic techniques for monitoring Earth’s surface deformations.

4.2.4 Precipitation Radar Radar can also be applied to measure the amount of rainfall. The TRMM provides the first detailed monitoring of tropical rainfall. The objective of the TRMM is to obtain three-dimensional rainfall distribution over land and oceans in the tropical belt between latitude 35° north and 35° south. Two-thirds of global rain falls within this tropical belt, and knowledge of climate processes here is important for understanding climate processes and changes on a global scale.

In addition to the precipitation radar, TRMM carries instruments for measuring radiance from clouds and a lightning sensor.

4.2.5 Light Detection and Ranging Light detection and ranging (lidar) refers to laser-based RS. Lidar uses principles very similar to those used in radar. The main difference is the difference in wavelength: radar uses microwaves whereas lidar uses visible light. In fact, the term lidar is a generic term used for a variety of sensors operating on different concepts. Going into detail for each of them would be beyond the scope of this article. For more information we refer to, for instance, Kramer.\(^8\) The main applications are measuring distance (height), movement, and chemical composition. By measuring the intensity, polarization, and spectral properties of the return signal as a function of time, one can obtain information on the properties of the atmosphere.

**Light Detection and Ranging Applications\(^8\)**

- Atmospheric research: meteorology, climatology, boundary layer physics, pollution, visibility, radiative budget, atmospheric dynamics and chemistry (composition).
- Solid-Earth research: crustal movement, gravity field, Earth kinematics and terrain mapping [digital terrain/elevation model (DTM/DEM)].
- Precise orbit determination.

Lidars are active instruments and can operate day and night. A disadvantage is that lidars cannot penetrate through optically thick layers (clouds).
5 PLATFORMS FOR REMOTE SENSING

Soon after the invention of photography, cameras were taken into the sky and aerial photography was born. Even today cameras and sensors are carried on anything that can observe the Earth at altitudes ranging from 1 m to about 30 km. Airborne RS is still extensively used, and will probably never disappear altogether, even though one might be inclined to think so in this modern age of space flight and technology. The reason for this is that airborne RS and satellite RS complement each other rather than compete with each other. Also, although this article deals mainly with satellite RS, it will be interesting to list a number of properties of both airborne and satellite RS next to each other.

5.1 Aircraft

Above 300 m we enter the realm of the aircraft. Virtually every type of existing aeroplane has been used, at some time or other, for the purpose of Earth observation. There is no such thing as the universal plane for RS; each plane has its own specific advantages and disadvantages. In the early days, the main problem was to fly high enough in order to cover large enough areas. Satellite images became available at the beginning of the 1970s, and a new niche was found: the highly specialized pinpointed analysis of areas within satellite coverage. The demand widened to require a new generation of slow-flying aircraft at low altitudes providing specialized cover for individual customers, and often operated by the users themselves.

In recent years, the “minimum” aircraft, or micro-light, has entered the field as a slow-flying camera platform. These new aircraft continue to surprise us, and several have been designed recently with work rather than sport in mind. They may yet gain our esteem in this respect.

Small, single-engined light aircraft have long been the workhorses in oblique and vertical aerial photography. The altitude of these planes is usually below 3000 m, and limited to 4500 m, flying for single projects.

The next step up is the light twin-engined aircraft, operating at altitudes ranging from 900 to 6000 m for the piston-engined twins to 7500 m for the turbocharged piston-engined aircraft. It offers larger carrying capabilities for payloads, faster speeds, better attitude control, offering a stable platform, better climbing performance, and better safety because of the second engine. Although there is some overlap with the earlier mentioned aircraft, this comes at the expense of higher investment and maintenance costs.

Pressurized turbo-prop aircraft are operated at altitudes from 4500 to around 10 000 m. Although high in capital cost, the scarcity or expense of aviation gasoline in many countries makes the turbo-prop, which uses kerosene as fuel, attractive as a survey aircraft. Airports everywhere are now geared up to jet aircraft and keep large quantities of fuel on hand for large airliners, making life easier for the turbo-prop than for the piston-engined aircraft.

Above 9000 m, the pure jet aircraft is the only platform available. The maximum altitude of these aircraft is in the region of 16 000 m. The top of the league is held by special reconnaissance aircraft, such as the beautifully sinister Lockheed SR71 Blackbird, capable of flying at altitudes in excess of 26 km!

Next in line, although not really an aircraft in the strict sense, is the Space Shuttle, operating at heights between 200 and 300 km. Several cameras, electronic scanners, and radar systems have flown on-board the Space Shuttle. The main emphasis in the past has been aerial photography. These days, however, it is more often on electronic sensing than on photography.

5.2 Drones

These aircraft, which look and act like outsized model aeroplanes, have been around for some time. Drones, also called remotely piloted vehicles or aircraft or unmanned aerial vehicles (UAV), are currently very much under development.

Drones have several advantages over ordinary aeroplanes:

- They are easy to deploy, control and recover.
- They are becoming cheaper to build as the state of the art improves and off-the-shelf technology becomes the norm.
- They are small and lightweight, and can be easily transported to any location.
- They require no pilot on-board and can fly, for instance, over enemy territory without fear of loss of life, or they can fly very high without the need for a pressurized cabin.
- They can fly autonomously, and be programmed to fly predetermined flight paths, using satellite navigation systems.
- They can fly nonstop, sometimes even for days.

NASA is has its experimental Pathfinder and Centurion planes in its Environmental Research Aircraft and Sensor Technology (ERAST) program. The planes are powered by solar energy. NASA wants those planes to go “slower, higher, and longer”. Eventually these planes will fly as slowly as 24 km h⁻¹, at altitudes of 30 km, for missions lasting as long as 4 days, carrying an instrument payload of about 90 kg.
The military also have their UAV programs for airborne reconnaissance using planes with catchy names such as Hunter, Predator, Global Hawk, and Dark Star.

Already the communications world has shown interest in this type of plane. Such a plane could circle a large city, serving as a relay station for communication channels. As such it would be a compromise between an Earth-bound network of transmitters and a satellite communication system.

The drones, together with small-satellite technology, have a great future for the communications and Earth observation businesses.

5.3 (Stratospheric) Balloons

Balloons have been used for decades to conduct scientific studies. While the basics of ballooning have not changed, the balloon size has increased and their reliability has improved greatly. Stratospheric balloons are ideal for making observations from the “edge of the atmosphere”. They go as high as 40 km, where it is too high for any plane and too low for any satellite. Balloons are made of thin 20-μm polyethylene material, about the same thickness as ordinary sandwich wrap. The balloon system includes a balloon, a parachute, and the payload that contains the instruments to conduct the experiment. Balloon payloads provide us with information on the atmosphere, the universe, the Sun and the near-Earth and space environment.

A balloon flight mission is relatively simple. The balloon is partially filled with helium and launched with the payload suspended beneath it. As the balloon rises, the helium expands and fills out the balloon until it reaches its peak altitude 2–3 h after launch. A major disadvantage of balloons is that they cannot be steered, the path being determined by wind direction only.

Unique Features of Balloons

- Balloons are inexpensive.
- Balloons offer a quick response method for performing scientific investigations.
- They can be readied for flight in as little as 6 months.
- Balloons are mobile, meaning that they can be launched where the scientist needs to conduct the experiment.
- A balloon can carry a payload weighing as much as 4000 kg.
- They can fly to an altitude of 42 km.
- Flights last an average of 12–24 h.
- Some special-purpose, long-duration balloon flights have lasted more than 2 weeks.

5.4 Sounding Rockets

The space age for RS received its first boost in 1891, when a patent was granted to Ludwig Rahrmann of Germany for a “New or Improved Apparatus for Obtaining Bird’s Eye Photographic Views”. The apparatus was a rocket-propelled camera system that was recovered by parachute. Sounding rockets are still being used to “fill the gap” between balloons and satellites. Typically they will be launched up to 250 km height and make a fall back to Earth by parachute, in the meantime taking measurements. The overall time in space is brief, typically 5–20 min. Sounding rockets are mainly used for studying the upper atmosphere chemistry. They provide the only platform with which direct in situ measurements can be made in these regions.

Furthermore, suborbital flights play a crucial role in the development and testing of instruments that ultimately lead to experiments on space missions.

Unique Features of Sounding Rockets

- quick, low-cost access to high altitudes where observations can be made of radiation at wavelengths absorbed by the Earth’s atmosphere;
- direct access to the mesosphere and lower thermosphere (40–150 km);
- low cost;
- rapid response times for examining new phenomena;
- flight of payloads especially crafted to study specific phenomena;
- relatively large payload masses can be carried;
- provision of several minutes of micro-gravity;
- ability to use the Earth’s limb as an occulting disk to permit observations close to the Sun;
- ability to tailor payloads to study specific targets;
- access to remote sites;
- long dwell times at apogee;
- slow vehicle speed with respect to the ambient medium;
- collection of vertical parameter profiles;
- ability to recover and refly instruments.

5.5 Vessels

Bathymetry is the measurement of ocean floor topography. Generally, a satellite cannot perform bathymetry directly, simply because most of the electromagnetic energy is absorbed by the water. There are two exceptions. One is the bathymetry of shallow coastal zones where some of the energy does reach the bottom, and reaches the top surface again. The other technique is based on the fact that the top surface reflects, to a certain extent, the height of the ocean floor; the topography can then be measured by using altimetry. First maps of the
ocean floors were generated around 1978 using data from the Seasat satellite.

Bathymetry can best be performed using sonar (ultrasound) on-board a vessel. Unfortunately, this is a time-consuming technique, and large portions of the Earth’s ocean floor still remain unexplored.

6 EARTH OBSERVATION SATELLITES AND SENSORS

There have been many Earth observation satellites since the 1960s, too many to mention them all. Just a few typical examples will be chosen and described here.

The satellites will be categorized according to the spatial resolution of their sensors. Some satellites will carry a number of different sensors, in which case the satellite is listed under the category of what is regarded as its most important or most interesting sensor for Earth observation. Next to the low, medium, and high spatial resolution categories, there are two special categories, imaging spectrometry and radar satellites.

In addition to RS instruments, satellites carry a host of other instruments (see Figure 12). Important for RS are instruments for orbital and attitude measurement and orbital and attitude control. The orbital position and velocity may be measured by means of

- ground tracking stations
- on-board reception of a satellite navigation system.

A satellite may measure its own attitude (orientation in space) in the roll, pitch, and yaw planes by means of

- inertial reference units, such as gyroscopes
- tracking the position of known stars
- Earth-horizon scanning sensors.

Once the orbital position and satellite attitude have been determined, ground-based computers at the mission control center calculate the necessary changes required for returning the satellite to its optimum configuration. Command signals may be sent to the satellite with instructions to use its thruster rockets to make the appropriate corrections.

A few typical examples of sensors in the following categories will be described:

- low-resolution sensors, with a spatial resolution larger than 100 m
- medium-resolution sensors, with a spatial resolution between 10 and 100 m

---

Figure 12 Schematic picture of the TIROS-N spacecraft carrying many different modules and instruments. Copyright NOAA.
- high-resolution sensors, with a spatial resolution better than 10 m
- imaging spectrometry sensors, with a high spectral resolution
- radar sensors, with an active microwave system.

It should be noted that the distinction between the low-, medium-, and high-resolution sensors is arbitrary and other groupings are possible. Sometimes the term very-high resolution is used for satellite sensors having a resolution better than a few meters. An explanation of some parameters is given in Table 4.

Good sources for the description of satellites and sensors are Kramer\textsuperscript{8} and Jane’s.\textsuperscript{20}

\textsuperscript{a} When a certain capability is not listed for a particular satellite and sensor, that does not necessarily mean that it does not have this capability; it just means that it is not listed. The list here is not meant to be complete; it is given as a comparative list. For completeness the reader is urged to consult one of the reference books mentioned above, or one of the many on-line resources.

### 6.1 Low-resolution Systems

Typically, these sensors have a spatial resolution larger than 100 m. They trade much detail in the image for large coverages, and frequent revisits. A global system of geo-stationary and polar orbiting satellites is used for the observation of global weather. Other satellites are used for oceanography and mapping phenomena on a continental or even global scale. For instance, images of the NOAA satellites are used for the food early warning system (FEWS) in Africa.

One major difference between the weather satellite group and the higher resolution groups is that these programs are the most operationally robust. Planning of replacement satellites typically is 10 years in advance, and if an operational satellite breaks down it can quickly be replaced.

Many of the medium- and high-resolution satellites also carry a wide-field, low-resolution sensor. With different sensors at different resolutions on one platform, the same phenomenon can easily be studied at different scales.

#### Characteristics of Low-resolution Sensors

- spatial resolution >100 m
- 3–7 spectral bands
- swath >500 km
- daily revisit capability.

Some low-resolution sensors are listed in Table 5.

### 6.1.1 Meteosat

Meteosat 1 was the first European meteorological geo-stationary satellite. Meteosat 5 is the currently the primary satellite, with Meteosat 6 as standby. Meteosat is controlled by Eumetsat, an international organization representing 17 European states.

Meteosat itself (Table 6) is part of a global network of geo-stationary meteorological satellites distributed around the equator. The other satellites are owned by the USA (GOES-E and GOES-W), Russia (GOMS), Japan (GMS), India (INSAT), and China (FENGYUN). The Meteosat satellite covers Europe, Africa, and the Atlantic Ocean. It observes the Earth in three spectral bands, the visible band, the WV band, and the TIR band at a low resolution of 2.5 km (5 km TIR). An image is provided every 30 min.

Meteosat Second Generation (MSG) will appear in 2000, together with the first polar orbiting Metop satellite.

### 6.1.2 National Oceanic and Atmospheric Administration Satellite

The workhorses of meteorology have been the NOAA satellites. The program has evolved over several
generations of satellites (TIROS, ESSA, TIROS-M, and TIROS-N, to the NOAA-KLM series), starting with TIROS-1 and culminating in the most recent NOAA-15 operational satellite. They have been the host for a shipload of different instruments for measuring the atmosphere’s temperature and humidity profiles, the Earth’s radiation budget, space environment, instruments for distress signal detection (search and rescue), instruments for relaying data from ground-based and airborne stations, and more (see Figure 12).

For Earth observation, the most interesting instrument is the AVHRR scanner. The AVHRR scans the Earth in five spectral bands: band 1 in the visible red around 0.6 μm, band 2 in the NIR around 0.9 μm, band 3 in the MWIR around 3.7 μm, and bands 4 and 5 in the TIR around 11 and 12 μm, respectively. This combination of bands makes the AVHRR suitable for a wide range of applications, from measurement of cloud coverage, to sea surface temperature, vegetation, land and sea ice. The disadvantage of the AVHRR is its coarse resolution of about 1 km at the nadir point. However, the major benefit of the AVHRR lies in its high temporal frequency of coverage. The NOAA satellites are operated in a two-satellite system. Both satellites are in a Sun-synchronous orbit; one satellite will always pass around noon and midnight and the other always passes in the morning and in the evening. The AVHRR sensors have an extreme FOV of 110°, and together they give a global coverage each day! Every spot on Earth is imaged at least twice each day, depending on latitude. It is the instrument for the observation of phenomena on a global scale, although, owing to its frequent revisit time, it is being used for many monitoring projects on a regional scale. See Figure 13 for an impression of the coverage over Europe of a single AVHRR scene.

The imagery of the AVHRR is also known by other names. High-resolution Picture Transmission (HRPT) is the digital real-time reception of the imagery by a ground station. There are over 500 HRPT receiving stations registered by the World Meteorological Organization (WMO) worldwide. The satellite can also be programmed to record a number of images. Such images, although having the same characteristics as HRPT, are called Local Area Coverage (LAC). Next to the 1-km resolution LAC, the satellite can resample the data on the fly to 4-km resolution Global Area Coverage (GAC). Finally, two bands of 4-km resolution imagery are transmitted by an analog weather fax signal from the satellite, which can

be received by relatively simple and low-cost equipment. This is called Automatic Picture Transmission (APT).

US President Clinton in May 1994 approved a long-mooted plan to combine NOAA’s polar orbiter with the military, halving the number of operational satellites to two, thus achieving a considerable reduction in operational costs. In about 2003, the American program will even merge with the European plan for polar orbiters, when the NOAA-N and Metop-1 satellites will join forces. Metop-2 and NOAA-N’ are scheduled for 2007.

Much more can be said about the characteristics, and use and abuse of the AVHRR imagery. Two excellent sources are Cracknell and Belward et al.

Note: NOAA-15 carries an improved sensor, the AVHRR/3. It has an extra spectral channel called band 3A at 1.6µm SWIR. The old band 3 is now called band 3B. The AVHRR images will still have five bands of information, because band 3A is switched on during the day and band 3B during the night. Furthermore, bands 1, 2, and 3A have increased sensitivity at low light and energy levels. The prime reason for this is to improve ice, snow and aerosol products produced from the data.

A description of NOAA systems is given in Table 7.

6.1.3 Resurs-O1

Maybe it is not altogether fair to list the Russian Resurs in the low-resolution category as it is actually equivalent to the US Landsat. However, the satellite is best known for its relatively cheap, large coverage images of the MSU-SK conical scanner. Receiving stations are located only in Russia and in Sweden. The Swedish Space Corporation Satellitbild also processes and distributes the images. Taking data from Resurs’ recorder allows it to reach a growing global market. With a swath of 760 km and a resolution of about 250 m, Resurs fills the gap between the 1-km resolution NOAA images and the 30-m resolution Landsat images.

Technical data are given in Table 8.

6.1.4 OrbView-2 or SeaStar/SeaWiFS

Launched on 1 August 1997, SeaStar will deliver multi-spectral ocean-color data to NASA for 5 years. This is the first time that the US Government has purchased global environmental data from a privately designed and operated RS satellite. SeaStar carries the SeaWiFS sea-viewing WiFS, which is a next generation of the Nimbus 7’s Coastal Zone Color Scanner (CZCS). SeaWiFS measures ocean surface-level productivity of phytoplankton and chlorophyll. However, SeaStar was originally designed for ocean color but was later changed to make it able to measure the higher radiances from land. Hence it provides a more environmentally stable vegetation index than that derived from NOAA’s AVHRR, which is inaccurate under hazy atmospheric conditions because of its single VIS and NIR channels.

Band 1 looks at gelbstoffe (yellow substance), bands 2 and 4 at chlorophyll, band 3 at pigment, and band 5 at suspended sediments. Bands 6, 7 and 8 look at atmospheric aerosols, and are provided for atmospheric corrections.

Technical data are given in Table 9.

6.2 Medium-resolution Systems

These sensors all have medium area coverage, a medium spatial resolution, a moderate revisit capability, and MS band characteristics comparable to those of the current Landsat and SPOT satellites.

The scale of the images of these satellites makes them especially suited for land management and land-use planning for extended areas (regions, countries,

continents). This explains why most of the satellites in this group are being funded and operated by governments. Unfortunately, the usefulness of these satellites is not accepted by the general public as it is for the weather satellites. This is the reason why these programs are not as operationally robust as the weather satellite programs. The failure of Landsat 6 was a major setback, and it took the USA another 6 years to replace the 15-year-old Landsat 5.

Most of these medium-resolution satellites are in a Sun-synchronous orbit.

Characteristics of Medium-resolution Satellites

- spatial resolution between 10 and 100 m
- 3–7 spectral bands
- swath between 50 and 200 km
- incidence angles from 0 to 30 degrees
- revisit 3 days and more.

Some medium-resolution satellites are listed in Table 10.

6.2.1 Landsat

The workhorses of Earth observation truly are the Landsat satellites, having been in operation since 1972. Landsat 5 has even been in operation for 15 years! The Landsat satellites were developed in the 1960s. Landsats 1–3 were enhanced versions of the Nimbus weather and research satellites, and were originally known as the ERTS. The moment Landsat 1 became operational, its vivid flow of revealing images was regarded as sensational by the early investigators. The quality of the images led to the information being put to immediate practical use. It became clear that they were directly relevant to the management of the world’s food, energy, and environment.

In 1981, as it became clear that the Landsat program would represent a total US investment of $1 billion, the US Reagan administration decided that the RS program must either die or be taken over by the private sector. Since that decision the Landsats have had a confusing history of ownerships. The latest state is that the Eros Data Center sells all multispectral scanner (MSS) and TM data older than 10 years, and Space Imaging EOSAT sells the new TM images. Landsat 7 data will be available at the low cost of reproduction only.

The Landsat satellites have flown the following sensors:

- The Return Beam Vidicon (RBV) Camera
- MSS
- TM.

The RBV basically consisted of three television cameras, each operating at their own spectral band. The ground resolution of the RBV was roughly 80 m, similar to that of the MSS. Even though the RBV had better geometric characteristics, the MSS was the sensor mostly used. One reason for this was that the RBV cameras exhibited many technical problems, but the main reason was that the MSS data were available in digital form (the signal from the RBV was an analog video signal). This made possible the direct further processing of the data, without the need for an intermediate conversion step. Applications of the MSS data have been widespread in many fields. Also, even though MSS images are not recorded any longer, the MSS data are still popular, first, because of the archive going back to the 1970s, MSS data can be used for monitoring changes, and second, because

the MSS data were put in the public domain and can be obtained for $200 per scene.

The TM, carried by Landsat 4 and 5, is the third sensor. Several major differences exist between the basic design of the MSS and the design of the TM. To improve the dwell time, i.e. the time a single detector has to take one measurement of one ground-cell, it uses an oscillating mirror and acquires data during both the forward and reverse sweeps of its mirror (see Figure 14). Furthermore, it has 16 detectors per band, such that 16 lines can be acquired at the same sweep of the mirror (four for the thermal band 6). At any one instant, surface radiation is sensed by a total of 100 TM detectors \([6 \times 16 + 4]\). Because of the longer dwell time, the TM offers improved radiometric sensitivity over the MSS. TM data are quantized to eight bits (256 possible radiance levels), whereas MSS data are quantized to six bits (64 levels). The TM has four times more levels over the same range than the MSS. Hence the radiometric resolution, the capability to notice small brightness differences between objects, has improved.

The first three Landsat satellites relied upon on-board recorders to store data until the satellite passed within range of a ground station. These recorders were often the first component to fail. Landsat 4 and 5 used a new communication system, called the Tracking and Data Relay Satellite (TDRS) system, which eliminates the need for on-board recorders. The TDRS system consists of satellites in a GEO and a centralized ground station. The first TDRS satellite was launched in 1983. The TDRS system made it possible to receive data in real time from the Landsat satellites all over the world, except for a small strip over Asia, India, and the Indian Ocean. Currently, because of problems with a transmitter on-board, the TDRS links have been lost, and Landsat 5 data can only be received by ground stations.

Landsat 4 was launched on 16 July 1982, but a failing power system prompted the launch of Landsat 5 2 years later on 1 March 1984.

The loss of Landsat 6 in October 1993 was a severe blow to the system and the USA must continue to rely on the aging Landsat 5. Both Landsat 4 and 5 have suffered from degrading subsystems and sensors and are expected to fail at any moment. The construction of Landsat 7 was set back considerably when two power supply units for its ETM+ sensor failed a test and had to be replaced. Landsat 7 was successfully launched on 15 April 1999.

Details of Landsat are given in Table 11.

6.2.2 Landsat 7

The Landsat 7 Data Policy Plan makes the Landsat 7 data available to all users at the cost of fulfilling requests. In fact, Landsat 7 was added to NASA’s EOS program, and there will be no distinct Landsat 8 as instruments will be carried within EOS after demonstration within the New Millennium Program (NMP). The NMP Earth Observer 1, NMP/EO-1, will carry a prototype Advanced Land Imager (ALI) for returning 10-m resolution PAN and 30-m resolution MS imagery. ALI has a pushbroom design, which is five times lighter, and which requires five times less power than the current Landsat sensors. NMP/EO-1 will fly less than 1 min ahead of Landsat 7, allowing accurate pair-wise comparison of the two technologies. Eventually, ALI will fly on the EOS AM-2 mission in 2004 to follow on from Landsat 7. Details of Landsat 7 are given in Table 12.

6.2.3 Système Pour l’Observation de la Terre 1–3

First named Système Probatoire d’Observation de la Terre (Test System for Earth Observation), but later renamed to Système Pour l’Observation de la Terre (System for Earth Observation), the SPOT system has been in operation since 1986. The SPOT satellites each carry two identical HRV sensors, consisting of CCD linear arrays. Essentially, all the points of one line
are imaged at the same time by the many detectors of the linear array. SPOT 1 was the first satellite to use this pushbroom technology. Pushbroom sensors avoid mechanical problems associated with moving scan mirrors. An additional advantage is that each detector has more time to perform a measurement of one ground-cell, which means it has a much longer dwell time, which in turn means that a better signal can be achieved.

A disadvantage of having so many detectors is that the sensitivities of all these detectors may be slightly different, requiring a calibration of thousands of detectors! A bad calibration of a pushbroom is visible as a pattern of vertical darker and brighter lines in the image, called vertical striping.

The SPOT sensors can be tilted from the normal downward viewing mode by ±27°, which offers the possibility of viewing objects from two different sides (see Figure 15). These stereo images can be used to determine the height of objects, or even the height of the terrain. The height model thus determined is referred to as a Digital Terrain Model (DTM).

SPOT 1 was already put in standby mode, but it has been activated again after SPOT 3 failed on 14 November 1996. SPOT 3 ran out of power when a wrong series of commands was sent to the satellite, and could not be recovered.

Details of SPOT sensors are given in Table 13.

**Figure 15** Pointing capabilities of the SPOT sensors, up to 27 degrees side-looking. The field of regard (FOR) is more than 950 km. Swath width is 60–80 km (after Kramer.⁸⁵)

6.2.4 Système Pour l’Observation de la Terre 4

SPOT 4 is considered a second-generation satellite, and carries a number of improvements over the older SPOTs:
1. An extra spectral band was added in the MWIR.
2. The PAN band has a narrower bandwidth.
3. Increased on-board storage capacity.
4. It carries a new wide FOV sensor for vegetation.
5. Its design life has been extended.
6. It carries an experimental laser communication device.

HRVIR instruments have superseded the HRV optical instruments on SPOT 1, 2, and 3. The HRVIR has three bands in the VIS and NIR spectrum and, in addition to the HRV channels, carries an additional band in the MWIR spectrum.

Another important addition to SPOT 4 is the VEGETATION instrument. This instrument is the first to use the HRVIR’s linear-array technology to produce high-quality imagery at lower resolution with greatly reduced distortion, compared with electromechanical sensors, such as the AVHRR and WiFS.

With a resolution of 1.15 km at nadir and a swath width of 2250 km, the VEGETATION instrument will cover almost all of the globe’s landmasses while orbiting the Earth 14 times a day. Only a few zones near the equator will be covered every other day. Areas above 35° latitude will be seen at least once daily. The HRVIR and VEGETATION have three identical spectral bands. The first band of VEGETATION is shifted towards the blue absorption band of chlorophyll (0.43–0.47 μm).

The laser inter-satellite communication device PASTEL is an experiment. The objective is to transmit imaging data from SPOT 4 to the ground over a high-rate laser link via the future Artemis geostationary data relay satellite of the European Space Agency (ESA).

With SPOT 5 scheduled to come on-stream around 2002, the SPOT family of Earth observation satellites still has many long years of service ahead of it. SPOT 5’s two high-resolution geometric (HRG) instruments will further enhance its performance. Spatial resolution will improve to 5 m. Further, SPOT Image plans to offer a 2.5-m sample distance product by combining two HRG images.

Details of SPOT 4 are given in Table 14.

6.2.5 Resource21

Resource21 is the name of a commercial RS information services company. Resource21 will combine satellite and aircraft RS to provide twice-weekly information products within hours of data collection, based on 10-m resolution MS imagery. The complete system will consist of four satellites. Every area on Earth will be visited by one of the satellites every three or four days, resulting in a revisit twice a week. In other words, the constellation will give a global coverage every three or four days at 10-m resolution. Details are given in Table 15.

The main application areas of Resource21 are agriculture (“precision farming”) and environment and natural resource monitoring.

At the time of writing it is not clear whether there is enough funding for continuation of the Resource21 program.

6.2.6 China/Brazil Earth Resources Satellite (CBERS)

The CBERS is also known as Ziyuan-1. The development and launch were realized by a trade agreement between China and Brazil. Its main imaging system has SPOT-like characteristics, using linear CCDs. Also a WFI will be provided. Plans provide for a second CBERS-2 satellite,

and CBERS-3 and -4 are projected to have a higher resolution. Details are given in Table 16.

6.2.7 Terra/Earth Observing System AM-1

EOS is the centerpiece of NASA’s Earth Science mission. The EOS AM-1 satellite, later renamed Terra, is the flagship of the fleet and will be launched in mid-1999. It carries 5 RS instruments including the moderate-resolution Imaging Spectroradiometer (MODIS) and the ASTER. ASTER is a high spectral resolution imaging spectrometer. The instrument is designed with three bands in the VIS and NIR spectral range with a 15-m resolution, six bands in the SWIR range with a 30-m resolution, and five bands in the TIR range with a 90-m spatial resolution. The VNIR and SWIR bands have a spectral bandwidth of the order of 10 nm. Simultaneously, a single band in the NIR range will be provided for along-track stereo viewing capability. The swath width of the image will be 60 km with a revisit time of about 5 days.

Also on EOS AM-1 (Table 17) is MODIS, which is planned as a land RS instrument with a high revisit capability. MODIS is mainly designed for global change research.

6.3 High-resolution Systems

This was once the exclusive domain of spy satellites in terms of resolution. Already in the 1960s spy satellites existed that had a resolution of better than 10 m. Civil high-resolution satellites had to wait until the very end of the 20th century. The major breakthrough was one of policy rather than technology. The US Land RS Act of 1992 concluded that a robust commercial satellite RS industry was important to the welfare of the USA and created a process for licensing private companies to develop, own, operate, and sell high-resolution data from Earth-observing satellites. Two years later, four licenses for 1-m systems were granted, and currently the companies involved are struggling to get their satellite first in space. This revolution promises to set off an explosion in the amount and use of image data. Applications that are not possible with today’s space or aircraft systems may well become routine.

Much is expected in the field of GIS technology. GIS databases will be constructed using the 1-m images, reducing reliance on out-of-date paper maps. Highly accurate topographic maps, called DTMs, can also be developed from the images and added to the databases. Because they cover large areas, high-resolution satellite images are expected to replace aerial photographs for certain types of detailed mapping such as gas pipeline routing, urban planning, and real estate.

Forestry and agriculture are also expected to benefit greatly from the increased resolution. The health and growing stage of crops can be monitored to areas within the field boundaries. This is known as "precision farming" and enables the farmer to apply water, fertilizer, and pesticides to specific areas in the field. In forestry, individual trees could be identified and mapped over enormous areas such as the Amazon. Tree species can be isolated by determining their signature in the electromagnetic spectrum.
The high-resolution imaging capability requires a change in instrument design to a pushbroom with a large telescope technique, resulting in a new spacecraft design. In contrast to the medium-resolution satellites, this group has limited MS coverage, or even just PAN capabilities. They do have extreme pointing capabilities to extend to potential imaging coverage. The pointing capability can also be used for last-minute reprogramming of the satellite if CC makes this necessary.

The private sector has shown an almost exclusive interest in high-resolution systems. Obviously, it is believed that these systems represent the space capability needed to create commercially valuable information products. On the other hand, the pure commercial nature with no government funding implies a high risk. This was demonstrated by the loss of the EarlyBird satellite and the resulting reorganization at the EarthWatch Company. Reliability and consistent service provision in any business depend very much on back-up solutions in case of need. Most companies in the high-resolution business have such a back-up satellite in store so as to be able to launch a replacement satellite at short notice. However, still, the loss of one satellite means a loss of millions of dollars, which may be considerable for a business just starting in this field.

Characteristics of High-resolution Satellites

- Spatial resolution better than 10 m
- 1–4 spectral bands
- Swath width less than 100 km
- Extreme pointing capabilities
- Revisit 3 days and more.

Some high-resolution satellites are listed in Table 18.

6.3.1 Indian Remote Sensing Satellite 1C and 1D

Having been the seventh nation to achieve orbital capability in July 1980, India is pressing ahead with an impressive national program aimed at developing launchers in addition to nationally produced communications, meteorological, and Earth resources satellites. Currently, India has more than a half a dozen RS satellites under development, intended for launch in the next decade. The entire fleet will be a mix of niche-role and multi-role satellites, which will join India’s existing constellation of polar orbiters. The US Company Space Imaging EOSAT plans to market imagery and data from all satellites that India expects to fly by 2005. The IRS-1C and -1D offer improved spatial and spectral resolution, on-board recording, stereo viewing capability and more frequent revisits. They carry three separate imaging sensors, the WiFS, the Linear Imaging Self-Scanning Sensor (LISS), and the high-resolution PAN sensor.

The WiFS provides regional imagery acquiring data with 800-km swaths at a coarse 188-m resolution in two spectral bands, VIS (620–680 nm) and NIR (770–860 nm), and will mainly be used for vegetation index mapping. The WiFS offers a rapid revisit time of 3 days.

LISS-3 serves the needs of MS imagery clients, possibly the largest of all current data user groups. LISS-3 acquires four bands (520–590, 620–680, 770–860, and 1550–1750 nm) with a 23.7-m spatial resolution, which makes it an ideal complement to data from the aging Landsat 5 TM sensor.

The most interesting of the three sensors is the PAN sensor with a resolution of 5.8 m, giving the IRS-1C and -1D the highest resolution of any civilian RS satellite currently in orbit. With its 5.8-m resolution, the IRS-1C and -1D can cover applications that require spatial detail and scene size between the 10-m SPOT satellites and the upcoming 1-m systems. The PAN sensor can be pointed off-nadir up to ±26° and thus offers stereo capabilities and a possible frequent revisit of about 5 days, depending on the latitude. Working together, the IRS-1C and -1D (Table 19) will also cater for users who need a rapid revisiting rate.

In late 1999, India will initiate a high-resolution mapping program with the launch of the IRS-P5, which has been dubbed Cartosat-1. It will acquire 2.5-m resolution PAN imagery. There seem to be plans to improve future Cartosat-2 to 1-m resolution.

6.3.2 Space Information – 2 m Resolution/KVR-1000

Data from the Russian KVR-1000 camera, flown on a Russian Cosmos satellite, is marketed under the name of SPIN-2 (Table 20). It provides high-resolution photography of the USA in accordance with a Russian–American contract. Currently SPIN-2 offers the world’s highest resolution, commercially available satellite imagery. SPIN-2 PAN imagery has a resolution of about 2 m. The data are single band with a spectral range between 510 and 760 nm. Individual scenes cover a large area of 40 by 180 km. Typically, the satellite is launched and takes images for 45 days, before it runs out of fresh film. The last mission was in February–March 1998. The archive goes back to 1980, and is available on-line via the Internet.

6.3.3 OrbView-3

 OrbView-3 (Table 21) will produce 1-m resolution PAN and 4-m resolution MS imagery.

6.3.4 Ikonos

The Ikonos satellite system (Table 22) was initiated as the Commercial Remote Sensing System (CRSS). The satellite will routinely collect 1-m PAN and 4-m MS imagery. Mapping North America’s largest 100 cities is an early priority. Unfortunately, the launch of the first Ikonos failed on 27 April 1999, because the protecting rocket nose fairing refused to come off, giving the satellite too much mass to reach orbit. Ikonos-2 will probably be launched later in 1999.

The OSA features a telescope with a 10-m focal length (folded optics design) and pushbroom detector technology. Simultaneous imaging in the PAN and MS modes is provided. A body-pointing technique for the entire spacecraft permits a pointing capability of ±30° in any direction.

Tasking commands can be modified up to 10 min before satellite contact, accommodating last-minute priorities or changing weather conditions.

6.3.5 QuickBird

QuickBird is (Table 23) the next-generation satellite of the EarlyBird satellite. Unfortunately, EarlyBird-1 was lost shortly after launch in December 1997. After its launch in late 1999, QuickBird-1 will offer 1-m resolution.

The sensor can be pointed off-axis ±30° into any direction, offering unprecedented stereo viewing capabilities.

6.3.6 Eros

Eros (Table 24) is the result of a joint venture between the USA and Israel. The Eros A+ satellite will have a resolution of about 1.8 m. The follow-up satellite Eros B will have a sub-meter resolution of about 80 cm.

6.4 Imaging Spectrometry Systems

These satellites will use a near-continuous spectrum to capture all of the information in the reflected radiance. This capability promises to make possible entirely new applications and to improve the accuracy of current MS analysis techniques. The technique is called imaging spectrometry, also referred to as imaging spectroscopy and hyperspectral imaging.

The push for imaging spectrometers has a long history in the geophysical field. Aircraft-based experiments have shown that measurements of the continuous spectrum allow greatly improved mineral identification. Clay minerals that cannot be distinguished by a human observer at a 1-m distance can be identified in hyperspectral images taken from a 20-km height! Recent airborne campaigns have also indicated significant improvements in the accuracy of vegetation identification and stress measurement.

The term “hyperspectral” is used for sensors capable of recording between 100 and 1000 bands. Future sensors, capable of recording more than 1000 spectral bands, are referred to as “ultraspectral” sensors.

Calibration and processing of hyperspectral data are difficult because of the large number of channels and the sheer amount of data. Algorithms developed specifically to make use of or cope with the high spectral dimensionality of hyperspectral data include:

- binary encoding
- waveform characterization
- wavelets
- artificial neural networks
- derivative analysis
- model inversion
- spectral feature fitting
- spectral angle mapping
- spectral unmixing
- constrained energy minimization
- classification
- cross-correlation spectral matching

Characteristics of Imaging Spectroscopy Satellites

- spatial resolution about 10–30 m
- more than 100 spectral bands
- swath width 5–15 km
- a revisit time of 3–7 days.

Some imaging spectrometry satellites are listed in Table 25.

6.4.1 OrbView-4

OrbView-4 (Table 26) will be the successor of the OrbView-3 high-resolution satellite. As with OrbView-3, OrbView-4’s high-resolution camera will acquire 1-m resolution PAN and 4-m resolution MS imagery. In addition, OrbView-4 will acquire hyperspectral imagery.

6.4.2 Earth Observing Satellite

Earth Observing (EO) satellite 1 is the New Millennium Program Earth Observing (NMP/EO-1) satellite. It is an experimental satellite carrying three advanced instruments as a technology demonstration. It carries the ALI, which will be used in conjunction with the ETM+ sensor (see Landsat 7 above) for comparison of the two sensors. In addition to the MS instrument it carries two hyperspectral instruments, the Hyperion and the Linear Etalon Imaging Spectrometer Atmospheric Corrector (LEISAC).

The focus of the Hyperion instrument is to provide high-quality calibrated data that can support the evaluation of hyperspectral technology for spaceborne EO missions. It provides hyperspectral imagery in the 0.4–2.5-µm region at continuous 10-nm intervals. The spatial resolution will be 30 m.

The LEISAC is intended to correct mainly for water vapor variations in the atmosphere using the information in the 890–1600-nm region at 2–6-nm intervals. In addition to atmospheric monitoring, LEISAC will also image the Earth at a spatial resolution of 250 m. The imaging data will be cross-referenced to the Hyperion data where the footprints overlap.

EO-1 (Table 27) is scheduled for launch at December 1999. The launch of EO-1 was delayed for 4 months in order to add a hyperspectral instrument to replace the one lost in the failure of the Lewis satellite. A flawed attitude control system and inadequate spacecraft monitoring by ground controllers doomed NASA’s Lewis imaging spectrometry satellite.

6.4.3 Aries-1

Aries-1 (Table 28) is a purely Australian initiative to build a hyperspectral satellite, mainly targeted at geological applications for the (Australian) mining business. Aries-1 will become operational in 2001.

6.5 Imaging Radio Detection and Ranging Systems

Radar’s cloud-penetrating, all-weather capability already makes it the instrument of necessity for many observational tasks. For areas usually covered by clouds (e.g. tropical areas), it may be the only instrument available for mapping tasks. However, radar has also proven invaluable in assessing floods and other disasters where weather conditions rule out optical images. Its sensitivity to soil moisture makes it useful for agriculture. Surface geometry is clearly visible in radar images, which is useful for identifying fault lines and other structures. Its penetration capabilities allow imaging topography under forested areas and mapping of subsurface structures.

The most important drawback of radar images is that the reflections of radar signals are very complex functions of the physical and structural properties, and also the water content of the target objects. This means that the interpretation of radar images is completely different to the interpretation of optical images. The complexity of radar images is responsible for the long development period faced by radar systems.

Characteristics of Radar Satellites

- spatial resolution between 10 and 100 m
- single or multiple (up to three) radar frequencies
- single or multiple polarization modes (HH, VV, HV, VH)
- swath 15–500 km
- revisit time 5–35 days.

Some radar satellites are listed in Table 29.

a AMI, Active Microwave Instrument; ASAR, Advanced Synthetic Aperture Radar; Envisat, Environmental Satellite.

6.5.1 European Remote Sensing Satellite

The ERS-1 satellite’s three primary all-weather instruments provide systematic, repetitive, global coverage of oceans, coastal zones, and polar ice caps, monitoring wave height and wavelengths, wind speed and direction, precise altitude, ice parameters, sea-surface temperature, cloud top temperature, CC, and atmospheric water vapor content.

1. The AMI can operate as a wind scatterometer or SAR.
2. The Along-track Scanning Radiometer and Microwave Sounder (ATSR-M) provides the most accurate sea-surface temperature to date.
3. The Radio Detection and Ranging Altimeter (RA) measures large-scale ocean and ice topography and wave heights.

The follow-on ERS-2 provides continuity until Envisat-1 appears. ERS-1 and -2 (Table 30) operated simultaneously from 15 August to May 1996, the first time that two identical civil SARs worked in tandem. The orbits were carefully phased to provide 1-day revisits, allowing the collection of interferometric SAR image pairs and improving temporal sampling. Although still working perfectly, lack of funding required it to be put on standby from May 1996. Extending ERS-2 operations beyond 2000 is under discussion.

In addition to the instruments mentioned above, ERS-2 also carried a Global Ozone Monitoring Experiment (GOME) to determine ozone and trace gases in the troposphere and stratosphere. The combination of images taken during the descending and ascending parts of the orbit can be used for stereoscopic viewing. The technique for determining height from stereo radar images is called radargrammetry.

6.5.2 Radarsat

Designed, constructed, launched, and operated by the Canadian Space Agency (CSA), Radarsat (Table 31) is the world’s most powerful commercial radar RS satellite totally dedicated to operational applications. Its C-band SAR has seven different modes of 10–100-m resolution and 50–500-km swath widths combined with 25 beam positions ranging from 10 to 60° incidence angles. Hence a wide variety of products can be offered to the customer. The Radarsat system is designed to operate with no backlog, so that all imagery received within a 24-h period can be processed and distributed within 24 h. For the customer this means that once the satellite has acquired the data, it can be on the desk within 3 days.

Radarsat-2 will have a resolution of 3 m.

6.5.3 Environmental Satellite

In May 2000, the ESA will launch Envisat-1 (Table 32), an advanced polar-orbiting Earth observation satellite, which will provide measurements of the atmosphere, ocean, land, and ice. Envisat-1 is a large satellite carrying a large number of sensors. The most important sensors for land applications are the ASAR, the MERIS, and the Advanced Along-track Scanning Radiometer (AATSR).

ASAR, operating at the C-band, ensures continuity with the image mode SAR and the wave mode of the ERS-1/2 AMI. It features enhanced capability in terms of coverage, a range of incidence angles, polarization, and modes of operation. The ERS-1 and -2 could only be switched on for 10 min each orbit, whereas the ASAR can take up to 30 min of high-resolution imagery each revolution.

In the normal image mode, the ASAR will generate high spatial resolution products (30 m) similar to the ERS SAR. It will image one of the seven swaths located over a range of incidence angles spanning from 15 to 45° in HH or VV polarization. In other modes it is capable of recording the cross-polarization modes (HV and VH). In addition to the 30-m resolution, it offers wide swath modes, providing images of a wider strip (405 km) with medium resolution (150 m).

The ESA is developing two spaceborne imaging spectrometers:

- MERIS to fly on Envisat-1
- Process Research by an Imaging Spectrometer (PRISM) on-board Envisat-2.

Although MERIS delivers only 15 bands, it is a fully fledged imaging spectrometer by design; the 15 bands are fully programmable in central wavelength and bandwidth.

PRISM will cover the 0.4–2.4μm wavelength range with a 10-nm contiguous sampling interval at a 32-m ground resolution. PRISM can be pointed in all directions, permitting measurement of the BRDF dependence of the wavelength.

**6.5.4 Shuttle Imaging Radar C/X SAR**

Together the Shuttle Imaging Radar C (SIR-C, built by NASA’s jet propulsion laboratory) and the X-band SAR (X-SAR, jointly built by Germany and Italy) (Table 33) comprise the world’s most advanced radar system ever flown. The system is capable of recording radar images at three different wavelengths (X, C, and L-bands) and in four different polarization modes (HH, VV, HV, and VH). The first mission was flown on-board the Space Shuttle flight STS-59 in April 1994 and the second mission was on-board STS-68 in September–October 1994. Roughly 20% of the Earth was imaged at up to 10-m resolution.

NASA plans a Shuttle Radio Detection and Ranging Topography Mission (SRTM) in September 1999 to create a global digital elevation map with 16-m height accuracy at 30-m horizontal intervals. SRTM will use the SIR-C antenna working interferometrically with an additional antenna on a 60-m long deployable mast. Approximately 80% of the Earth’s landmass (everything between 60° north and 56° south latitude) will be imaged in 1000 data takes.

original design lifetime was 2 years, but JERS-1 operated until October 1998, when a short-circuit in its solar panels immobilized it. The next Japanese radar system will be on-board the Advanced Land Observing Satellite (ALOS) to be launched in 2002. The new SAR will have multiple resolution, 10-m high-resolution and 100-m ScanSAR mode, multiple polarization modes (HH and VV), and a variable off-nadir pointing angle capability.

6.6 Future Systems

There is a push for ever-improving resolution: spatial, spectral, radiometric, and temporal resolution. The current trend of building constellations of smaller and smarter microsatellites will certainly be an important factor in this respect.

6.6.1 New Techniques

New techniques for measuring aspects of the Earth’s environment will emerge. NASA, for instance, has many innovative sensors and satellites under development. The Space Shuttles will continue to carry experimental sensors that will eventually be carried by operational systems in its Earth Science System. Three EO missions are defined carrying technologies that could revolutionize space-based Earth observations.

EO-1 is scheduled for launch in December 1999. It will demonstrate an ALI system and hyperspectral imaging technologies that may eventually replace the current measurement approach used by Landsat satellites.

EO-2 will fly an IR laser in the cargo bay of the Space Shuttle to demonstrate the capabilities of a space-based lidar to measure accurately atmospheric winds from the Earth’s surface to a height of about 15 km. This flight is scheduled for launch in early 2001.

EO-3 will be a geo-stationary system with new technologies such as

- a high-resolution thermal imaging sensor
- a synthetic aperture sounder
- a Fourier transform imaging spectrometer
- a tropospheric trace-gas imager.

Not all these sensors are new, but the idea of flying them in a GEO is new.

Future developments include the following:

- Earth observation will profit from the current boom in communication.
- Miniaturization of satellites to the size of a suitcase weighing 50 kg.
- Application of solid-state sensors and recorders.
- The application of constellations of EO satellites.
- New propulsion methods, e.g. the application of ion motors.
- New attitude control methods, e.g. magnetic torque.
- The application of laser/lidar from space.
- The use of P-band radar from space (currently not allowed by international law).
- The installation of high-resolution sensors in a GEO.

- The use of “new” orbits, e.g. the Lagrangian point L1 of the Sun–Earth system or the L4 point of the Earth–Moon system.
- The application of high-speed laser communication.
- The use of satellite-to-satellite communication.
- Earth observation from the ISS (see below).

6.6.2 The International Space Station

The ISS will offer unique observation capabilities. Its orbit covers 75% of the Earth’s surface, containing 95% of the Earth’s population. It will offer a long-term window on the world and, because astronauts always inhabit it, it offers unrivalled observational capabilities on disaster events. Telescopes can easily be pointed at disaster zones. Currently, the US Laboratory Window Observational Research Facility (WORF) is in the requirements, definition, and conceptual design phase. Many aspects of the Space Shuttle-based EO program will be considered in the design and operation of the WORF.

6.6.3 Future Missions

Tables 35 and 36 are intended to give the reader an impression of the missions that are scheduled for launch in the coming two years (last revision 22 June 1999).

7 REMOTE SENSING IMAGES

A remotely sensed image is a two-dimensional collection of samples. Each of its elements is a pixel (picture element) whose intensity is a DN value. The number of possible values is usually limited to 256 (8 bits) providing 256 brightness values called gray levels in the image.

The value of a pixel is literally the most visible characteristic of a sample. However, in addition to the value, each pixel carries a number of implicit characteristics. Each sample is a measurement taken at a certain location, at a certain time, measuring a certain property of the target object. The measured property is usually the amount of radiation received in a certain spectral range, and is determined by the design of the sensor. The value and the time of acquisition are recorded at the time of imaging. But what about the location of a sample? It appears that the Earth location of a pixel can be determined from its location in the image matrix, but this requires knowledge of the sensor design, of the satellite’s position and attitude, and of the shape and topography of the Earth itself. The process of determining the Earth location of pixels is referred to as geo-referencing.

The information content of digital images can be summarized as follows:

- Where?  Spatial information
- What?   Spectral (and other) information
- How much?  Radiometric information
- When?  Temporal information.

Both the sampling and the resolution in the spatial, spectral, radiometric, and temporal domains determine the amount of detail that can be observed from a digital image. Although there is a strong mathematical analogy in the concepts of resolution and sampling in these domains, many different factors play a role in this.
For well-balanced systems, the resolution will be of the same order of magnitude as the sampling intervals, which leads to confusion of these terms. For instance, often the term “temporal resolution” is used to describe the revisit capability of a remote sensor, when actually “temporal sampling” is meant.

Sampling is defined as the interval between successive measurements, and is determined by the following:

- **Spatial sampling** is determined by the sampling speed of the sensor and the spacing of the elements of the detector array (pushbroom).
- **Spectral sampling** is determined by the position of the center of the spectral bands. In MS sensors band placing is determined by the sensitivity of the detector and transmission function of whatever filter was applied. Only in hyperspectral instruments could one speak of spectral sampling, and it is then determined by the spacing of the elements of the detector array.
- **Radiometric sampling** is determined by the dynamic range of the sensor and the number of levels (quantizations) that the ADC can handle.
- **Temporal sampling** is determined by the orbit repeat cycle of the satellite, together with the off-axis pointing capability of the sensor.

Resolution is defined as the minimum separation between two objects at which they can still be discriminated, and is determined by the following factors:

- **Spatial resolution** is determined by the aperture (or photon catching area) of the detector and the quality of the optical system used. It can to a certain extent be expressed as a point spread function (PSF) or a MTF. The MTF is actually the Fourier transform of the PSF. The PSF reveals how much an image of an ideal point source is blurred by the sensor. It should be noted that the concept and use of a PSF only has meaning for linear systems. Practical systems hardly ever are such ideal linear systems. The “size” of both the PSF and SRF (see next point) functions is sometimes defined by taking the width at half of the maximum value of the function fwhm. The spatial resolution of a scanner system is referred to as the instantaneous field of view (IFOV).
- **Spectral resolution** is related to bandwidth and is determined by the SRF. The SRF plots the sensitivity of the sensor for all wavelengths. A wide skirt in this function is an indication of bad out-of-band rejection (see spectral accuracy below).
- **Radiometric resolution** is determined by the ability of the ADC to resolve different levels of input. In practice this is limited by the amount of noise present in the electronics. Noise levels can be expressed as the commonly used signal-to-noise ratio (SNR), which expresses noise level with respect to signal level. A more useful measure is to express the noise level as an equivalent input level to the sensor. Thus the noise can be expressed as the noise equivalent radiance (NER) or noise equivalent temperature difference (NE\(\Delta T\)). Basically the NER determines the smallest difference in input levels that can be discriminated by the sensor.
- **Temporal resolution** is determined by the dwell time of the sensor. If there is a considerable movement during the dwell time, this will be visible as a motion blur in the result. As the movement of satellites is smooth, very simple measures can be taken to reduce the amount of motion blur caused by the dwell time, e.g. by simply pointing the detector backwards during a scan.

The accuracy is defined as the exactness of the measurement, and is determined by the following factors:

- **Spatial accuracy** is determined by the mechanical stability of the sensor (scan mirror jitter, thermal stress, film stretch), the quality of the optical system (lens aberration), and pointing stability of the platform (attitude control).
- **Spectral accuracy** is determined by the band placing (accuracy of the central wavelength), and out-of-band rejection (spectral separation).
- **Radiometric accuracy** is determined by dark current or offset, nonlinearities in the response function, overload, cross-talk, etc. Furthermore, the response of a sensor may vary with the position in the image. A sensor may exhibit light falloff very much like in a photographic camera. Sensors may degrade with time (aging), and regular calibration is necessary in order to preserve a certain standard in absolute accuracy of the sensor.
- **Temporal accuracy** is not an issue in RS as normally the interval between the images is of the order of hours and days.

Resolution, sampling, and accuracy to a large extent determine the visible quality of images. However, there are additional external image quality factors, as follows:

- **Owing to transmission problems or recording problems** there may be missing or incomplete data (dropouts, dropped lines).
- **There may be additional noise from various external sources.** Spacecraft and sensors can be confused by what is called a single-event upset (SEU). SEUs
occur in space when a single high-energy particle hits the spacecraft electronics, disrupting the spacecraft’s normal operations.

- There may be unfavorable atmospheric conditions such as haze and CC.
- There may be differences in down-welling irradiance. For instance, the distance between the Earth and the Sun varies by approximately 1%, which causes a small difference in energy available to remote sensors over the year. Reflective properties can only be determined if the exact amount of down-welling energy is known. This is particularly important for airborne sensors where part of the energy is already lost by the amount of atmosphere overhead. Nowadays, many airborne systems also measure the down-welling energy in addition to the images. It should be noted that characterization of the down-welling irradiance is just as important, and in some respects more difficult, than the characterization of the up-welling measurement part of the sensor.
- There may be glint or hot-spots visible in the image, due to an unfavorable solar angle.

On satellite systems the bandwidth of the downlink enforces a practical limit on the amount of detail. The amount of data is proportional to

- the number of spatial samples (number of pixels, and lines)
- the number of spectral bands
- the number of radiometric levels (number of bits per sample)
- the revisit frequency
- the amount of auxiliary data in the telemetry.

This means that there is a simple tradeoff between these numbers. A satellite with a large coverage has only a limited pixel size. An imaging spectrometer cannot offer a high spatial resolution. High-resolution satellites offer only a limited number of bands, and so on. There is one exception to the rule, namely spaceborne photography. For instance, the KVR-1000 camera has a high resolution but at the same time it has a large coverage. Once in a while it drops a canister of exposed film, the equivalent of an enormous electronic transmission rate. Of course, this comes at a cost, too. Once all the film has been used, it is the end of the mission. The tradeoff between swath width, number of bands, and spatial resolution is immediately visible when we plot the spatial resolution of a number of satellites against the swath width. Figure 16 clearly shows the trade-off between resolution and swath width. High-resolution satellites have a small swath width; medium-resolution Landsat-like satellites have large swath widths. The SPIN-2, using a KVR-1000 camera, is also visible. For imaging spectrometry satellites the limiting factor will be the number of bands.

Future high-speed satellite-to-satellite communications links may increase the downlink data-rate capabilities, relieving some of the constraints on the data volume.

The tradeoff between resolutions also implies that the ideal RS system does not exist! If a good sensor is good

![Figure 16](image-url)  
**Figure 16** Spatial resolution versus swath width for a number of satellites. The downlink capacity of a satellite imposes a practical limit on the data transfer rate, which means there is a trade-off between spatial resolution, swath width, and number of bands. Indicated by ellipses are four typical classes of satellites. The low-resolution systems are not included in this figure.
for one application this does not mean that it is suitable for another. That is the reason why there are so many systems; they complement each other rather than being competitors in the same market. Even if different sensors have similar characteristics, this is good for the user, because it offers additional opportunities for acquisition. Apart from that, simple economics states that prices go down where there is competition.

7.1 What Type of Satellite Image?

Selecting satellite images for specific projects is not an easy task. Many factors determine whether a satellite image will meet the requirements of a project within the boundary conditions. As pointed out before, trade-offs exist between spatial resolution, spatial coverage, number of spectral bands, radiometric resolution, temporal coverage, and revisit time. The Netherlands, for instance, is 90% covered by two full-scene 30-m resolution Landsat TM images. If the project were to require the 20-m resolution of MS/SPOT, then one would require about 30 SPOT images, costing 10 times more than the Landsat images. Also, the required computing power for processing the images (storage and CPU) would increase by a factor of 10. All this is at the loss of a few spectral bands.

However, there are more factors. For instance, The Netherlands is one of the places where the chance of obtaining one cloud-free image during 10 days is less than 10%. In order to cover the entire country of The Netherlands one might end up having to buy as many as 20 full-frame and quarter-scene Landsat TM images. Clearly, these images can never be acquired in a single day, or even in a single season, and maybe not even in a single year, as the satellite only passes once every 16 days. Obviously, this will result in a number of images having very different lighting conditions, because of the different solar angles in winter, spring, summer, and fall. Also, there will be a large variation in the growing stages of the crops and natural vegetation. All this means that, if one wants to produce an image map of The Netherlands from satellite images, a considerable amount of time will have to be spent on radiometric processing and carefully stitching the images together. The stitching must be done in such a way that the differences between the individual images are not too obvious in the final result.

Of course it is possible to acquire a satellite image of the entire country of The Netherlands in a single day by selecting NOAA imagery. One can even have two images each day, but this is at the expense of the resolution of only 1 km.

7.2 Which Image?

Once it is settled what type of imagery one requires for a project, it must be decided which images meet the requirements of the project. Fortunately, many data providers have on-line catalogs on the Internet. The user can enter search queries and the system will return information about the availability of imagery. Each entry will list the meta-data (information about the image data) and very often a quick-look (the satellite image in reduced format). The query form has the following entries:

- Acquisition date. The required acquisition date can be entered as a single date or a range of dates. Sometimes a seasonal range can be entered enabling queries such as “show all April images for the years 1980–1990”.
- Geographic coverage. The required location can be entered as a single point, a box (by entering two points), or a free polygon (by entering many points). Sometimes the scene center can be entered as a path–row pair or an orbit–frame pair.
- Cloud cover (CC). Of course, unless one is a meteorologist, a fully clouded image is worthless, but sometimes one has to accept some clouds simply because cloud-free images are not available. CC can be listed for the entire image, or even for each quarter of the image. Values usually range from 0% (cloud-free) to 100% (fully clouded). Some systems have special codes for cloud (and snow) cover; SPOT designates cloud-free images with an A, codes B, C, and D are used for partly clouded images, and a fully clouded image is coded E. Further, remember that 10% CC is only good if that single cloud is not over the study-area! The quick-look image is an almost mandatory item of the image database.

The catalog system returns a list of images matching the query. In addition to the acquisition date, geographic coverage, and CC, the following items are worth noting:

- Technical quality. This is actually the figure for the overall performance of the sensor, platform, transmission, and preprocessing. If this figure is low, one has to be careful; using such an image may yield surprises during later processing and interpretation. However, this does not mean that an image with a low technical quality should not be used at all. This figure should simply be regarded as a sort of warranty statement by the data supplier.
- Quick-look image. This is probably the most interesting part of the image database. The quick-look image is a degraded version of the original image. It is poor enough to prevent its misuse for analysis, but good enough for recognizing features in the area of interest and for checking for clouds and haze.
7.3 Image Processing and Image Products

Effective management by the use of RS data relies on accurate and timely information. The need to manage our activities and their influence on our environment drives an ever-increasing demand for high-quality information.

In order to achieve the highest quality, the data received from the satellite has to undergo a number of preprocessing and processing steps. Preprocessing corrects for known errors and distortions. The result of the preprocessing is image data that can be directly used for further distribution, analysis, and interpretation. However, in order to arrive at project-specific information, further processing may be needed.

Preprocessing steps involve the following:

- **Radiometric correction.** During the radiometric correction the DN values are transformed into physical units. Noise and systematic errors are removed as much as possible. Radiometric correction relies on the calibration data of the sensor.

- **Geometric correction.** Although the Earth location of each image point is implicitly known by its relative orientation in the image matrix, most images are transformed in such a way that the image coordinates carry a direct relationship with a map projection. The process of determining the transformation is referred to as geo-referencing; the transformed image is then said to be geo-coded.

- **Atmospheric correction.** Actually, the correction for atmospheric effects is also some form of radiometric correction, as it operates on the values only. However, the parameters and models used for the atmospheric corrections are so different and so complex that it is justified to separate these corrections from the radiometric correction. An accurate atmospheric correction requires knowledge of the state of the atmosphere at the time of acquisition; parameters such as aerosol, water vapor, and ozone content should be recorded together with the image data. Unfortunately, it is not yet common practice to supply these atmospheric data with the image data. The bare minimum atmospheric correction takes care of haze and skylight.

These corrections are not necessarily done at one and the same location. From satellite to end-user the data may go through one or more of the following facilities:

- **The Ground Station or Data Acquisition Facility.** Acquires the raw (telemetry) data transmitted by the satellite, and records it directly on disks for later backup on digital media.

- **The Mobile Ground Station.** Fills gaps, but also an efficient solution to fill the gaps, and generates quick-look data, stores data and meta-data in a catalog, allows for catalog consultation, services user orders, and disseminates the data in a processed form on exchange media such as computer-compatible tape (CCT), CD-ROM, or 8-mm digital video tape.

- **The Archiving Center.** Sometimes the archiving and dissemination functions are separated from the processing facility into an archiving center.

- **The Value Added Facility or Value Added Resellers.** These facilities or companies process the standard digital images to value-added digital image products such as ortho-images, mosaics of geocoded images, and digital elevation models (DEMs).

- **The User Support Services.** Help the user with catalog lookups, with advice on images and image products, and with satellite programming requests if the user wants the satellite to record new data. User services enable the users to order products, and offer after-sales service.

- **The Clearinghouse or Data Warehouse.** A one-stop counter for all sorts of spatial data.

The above-mentioned facilities are not always strictly separated; combinations of functions are possible such as the European processing and archiving facilities (PAFs). The resulting image data are available in a number of processed image products. So-called processing levels designate these products. In most standard imagery the following levels can be found:

- **Level 1A.** The “raw” image data; only the bare minimum of radiometric corrections is performed.

- **Level 1B.** The standard image data; additional corrections to level 1A are performed, such as corrections for Earth rotation (skew) and curvature. Sufficient auxiliary data are added to enable the user to perform the geo-coding themselves.

These standard products are available as full scene or, to reduce cost, as a quarter scene, or floating scene, and sometimes any subset may be selected from the image. However, one has to realize that many still regard the
"subset" as a value-added product, which, consequently, should cost a "value-added" price. This may change in the near future as flexibility of the archiving centers and the software increases.

The next levels 2A to 2C are the geo-coded products. A higher level means a higher geometric accuracy. These products usually cost a factor of two more, so if the end-user has the equipment (and the time) usually they will perform these steps at their own facilities.

- Level 2A, the systematically geometric corrected product. Only the location and attitude of the satellite are used for the geo-coding. Accuracy is of the order of a few pixels.
- Level 2B, the precision geometric corrected product. To improve accuracy points in the image are related to map locations [ground control point (GCP)]. Accuracy is of the order of 1 pixel on flat terrain.
- Level 2C, the ortho-image. Level 2B does not yet take into account the displacement caused by height in the terrain. Level 2C uses GCP and a DEM or DTM to reach an overall accuracy of less than 1 pixel.

It should be noted that although levels 1A and 1B are often used as a de facto standard, there is no such definition for the higher levels. Levels 2A to 2C are often used, but many other designations and terms are used for various other products, e.g.

- Fused products. For instance, PAN and MS data can be integrated to obtain data that have both a high spatial resolution and a high spectral information content.
- Stereo products. A pair of images taken from different incident angles to permit enable stereoscopy and height measurement.
- Multitemporal product. Images from the same location but from different dates.
- Many levels exist for radar imagery, such as single-look complex (SLC), multi-look complex (MLC), and precision image (PRI).
- Mosaic products, which are composed of many different images stitched together. Studies spanning large areas may require such products. These products require the utmost radiometric "matching" of the scenes, the greatest accuracy of geometric correction, and the highest storage capacity.
- Image maps. These are satellite image data presented in a map-like way; they contain a coordinate grid, a legend, meta-data, etc.

7.3.1 Committee on Earth Observation Satellites

The Committee on Earth Observation Satellites (CEOS) was created in 1984 as a result of the international Economic Summit of Industrialized Nations and serves as the focal point for international coordination of space-related Earth observation activities. Policy and technical issues of common interest related to the whole spectrum of Earth observation satellite missions and data received from such missions are addressed. CEOS encourages complementarity and compatibility among space-borne EO systems through coordination in mission planning, promotion of full and nondiscriminatory data access, setting of data product standards, and development of compatible data products, services, and applications.

7.3.2 Committee on Earth Observation Satellites

International Directory Network

The CEOS International Directory Network (IDN) is an international effort to assist researchers in locating information on available data sets. The IDN provides open, on-line access to information on worldwide scientific data including Earth sciences (geoscience, hydrographic, biospheric, satellite RS, atmospheric sciences), space physics, solar physics, planetary science, and astronomy/astrophysics. The IDN describes data held by university departments, government agencies, and other organizations. The search for data sets can be done online via one of the local nodes of the IDN, e.g. on NASA's Global Change Master Directory.

For the end-user, CEOS offers two obvious advantages:

- Data query. Descriptions of data sets can be queried through the IDN.
- Data format. Most satellite data comply with the CEOS "standard".

However, the last point does not mean that all the data come in the same form! The CEOS format defines a structure for the data and a standard for a description of the meta-data that comes together with the satellite data, but it does not say anything about the meaning of all the entries in the meta-data and the way in which the meta-data should be used. The meta-data information can be anything related to the (image) data, including:

- the data acquisition facility
- the processing facility
- software version
- date and time of acquisition
- size; number of bands, lines, and pixels per line
- calibration data
8 CONCLUSION

Pictures of the Earth from space are marvellous images. These images are not just beautiful to look at; they can also be used for a diversity of applications in daily life. With these images floods can be predicted or icebergs detected. With these images a geologist can discriminate details which lead to underground water stores and new deposits of mineral resources. With these images, maps can be made of the vegetation in large areas. Many more applications are possible.

Examining the Earth from space is a wonderful means and a powerful tool. Most scientists are enthusiastic. Some scientists air their criticisms and refuse to see the potential that these images can offer. The best way is to see for yourself and judge whether these images offer anything else besides just beauty, and to try to recognize and understand the many details these images show, possibly aided by proven image processing and GIS techniques.

Earth observation is still in its infancy and the big “boom” of RS is yet to come. Possibly, in the near future, the Earth will be circled by constellations of small and low-cost RS satellites that meticulously monitor all aspects of the Earth’s surface and atmosphere. The deluge of data that these systems will deliver will hopefully help us to understand the processes that rule this tiny spaceship called Earth.

Sea Ice Monitoring by Remote Sensing

Stein Sandven, Ola M. Johannessen, and Kjell Kloster
Nansen Environmental and Remote Sensing Centre, Bergen, Norway

INTRODUCTION

1.1 The Role of Sea Ice in the Climate and Weather System

Sea ice is defined as ice which is formed as a result of freezing of seawater. Sea ice occurs at the surface of the ocean in areas where the surface temperature is cooled to the freezing point, which is about \(-1.8\) °C for sea water with a salinity of about 35 parts per thousand. Ice formed in lakes and rivers and icebergs coming from glaciers and ice sheets are not defined as sea ice.

Monitoring by remote sensing is defined as any measurement technique which can be used to observe sea ice repeatedly by instruments on board earth observation satellites. Monitoring also includes the process of making observational data available for users a short time after the observations have been obtained (i.e. a few hours). Remote sensing of ice can also be done with aircraft, submarines and other vehicles, but these techniques are not discussed in this article.

1 INTRODUCTION

1.1 The Role of Sea Ice in the Climate and Weather System

Sea ice is a part of the cryosphere which interacts continuously with the underlying oceans and the overlying atmosphere. The growth and decay of sea ice occur on a seasonal cycle at the surface of the ocean at high latitudes. As much as \(3 \times 10^7\) km² of the earth's surface can be covered by sea ice. In the Northern Hemisphere, the extent of sea ice (area enclosed by the ice boundary) fluctuates each year from a minimum in September, when most of the ice is confined to the central Arctic Ocean, Greenland Sea and Canadian Archipelago, to a maximum in March, when the ice covers almost the entire Arctic Ocean and many adjacent seas. In the Southern Hemisphere, the annual fluctuation is even greater, from a minimum in February to a maximum in September when the ice surrounds the Antarctic continent and extends equatorward.
to 55–65°S. Figure 1(a–d) shows an example of the maximum and minimum ice extent observed by PMW satellite data.

The largest volume of sea ice is found in the northern hemisphere in March, $0.05 \times 10^6$ km$^3$, which is nearly twice the maximum ice volume in the southern hemisphere. The reason for this is the mean thickness of the Arctic sea ice, which is about 3 m, whereas the mean thickness of the Antarctic sea ice is 1–1.5 m.

Sea ice research and monitoring are important issues for many countries at high latitudes, including those who operate in Antarctica. Sea ice imposes severe restrictions on ship traffic in Arctic countries, it is a sensitive climate indicator and it plays an important role in exploration and exploitation of marine resources.

Sea ice has many roles in the global climate system. For one, it serves as an effective insulator between the ocean and the atmosphere, restricting the exchange of heat, mass, momentum and chemical constituents. During winter when there is a large temperature difference between the cold atmosphere and the relatively warm ocean surface, ocean-to-atmosphere heat transfer is essentially limited to areas of open water and thin ice within the pack. The winter flux of oceanic heat to the atmosphere from open water can be two orders of magnitude larger than the heat flux through an adjacent thick ice cover. As a result, the distribution of open water and thin ice is particularly important to the regional heat balance.

Another important role of sea ice in the global climate system is that it affects surface albedo. Ice-free ocean generally has albedos below 10–15%, whereas snow-covered sea ice albedos average about 80%. A fresh snow cover on the ice can increase the surface albedo to values as high as 98%, whereas melt ponds can decrease the ice albedo to as low
as 20%. Because the albedo of snow-covered sea ice is high, relative to that of open water, the presence of sea ice considerably reduces the amount of solar radiation absorbed at the earth’s surface. This is most significant in summer, when the insolation, or solar heating, is high.

Sea ice processes also affect oceanic circulation directly by the rejection of salt to the underlying ocean during ice growth. This increases the density of the water directly under the ice, thereby inducing convection that tends to deepen the mixed layer. This convection contributes to driving the thermohaline circulation of the ocean and, in regions with density structures that were initially weak or unstable, can lead to overturning and deep water formation. Much of the world oceans’ deep and bottom water is believed to be formed in polar latitudes by these mechanisms. Conversely, the input of relatively fresh water to the ocean during ice melt periods tends to increase the stability of the upper layer of the ocean, inhibiting convection. Furthermore, the net equatorward transport of ice in each hemisphere produces a positive freshwater transport and a negative heat transport.

On a hemispheric scale, the seasonal variability of ice extent and ice edge location is controlled by atmospheric and oceanic forcing, which include ocean temperature and salinity and atmospheric temperature and winds. The location of the ice edge will in turn feed back on several atmospheric and oceanic processes, which have an effect on the regional weather, such as the generation of polar lows. On a regional scale surface roughness of the ice and the drag coefficient depend upon ridging and rafting, both of which can be produced by wind- or wave-induced ice convergence. Ice observation is therefore important for weather forecasts at high latitudes.

Data from polar orbiting satellites are used extensively in research and in monitoring of sea ice extent and other ice parameters. Ice thickness, which is another important ice parameter, cannot be measured directly by any spaceborne instrument today. The key objective in sea ice science during the next decade is to achieve the capability for synoptically measuring sea ice thickness in both hemispheres. Data on ice thickness are very sparse, especially in Antarctica. Our estimates of sea ice volume, which are mainly based on model results owing to a lack of data, can have errors of ±50%. In the Arctic there are a few synoptic surveys of ice thickness obtained by submarine sonar and point measurements from expeditions and drifting ice stations. The data sets available provide some information about regional and seasonal variability, but they are too sparse to provide any information about temporal changes.

General circulation models predict enhanced climatic warming in polar areas, and this should be reflected in a decreased mean sea ice thickness and possible changes in the intensity of pressure ridging. Without a technique to map sea ice thickness routinely, however, such changes cannot be detected. Only a satellite-borne method can achieve the required coverage in time and space without prohibitive cost, and this will have to be a technique which measures topography directly, since imaging methods (active microwave (AMW) PMW, visual, thermal infrared (TIR)) do not yield thickness but only an identification of ice type.

1.2 Sea Ice as a Barrier for Ship Traffic, Fisheries and Offshore Operations

The presence of sea ice represents a major limitation for ships and offshore operations in high latitudes in both hemispheres. The sea ice, which is on average 2–3 m thick, can only be penetrated by ice-strengthened vessels or icebreakers with sufficient ice class. Most ships and fishing vessels are not ice-strengthened and must therefore avoid all ice areas. In many cases, when the ice concentration is 100% and the ice pressure is high, even the most powerful icebreakers can have problems moving forward through the icepack. Offshore platforms for ice-covered areas must have much stronger construction than that required in ice-free waters. Also, harbors and loading terminals on the coast require stronger construction in areas of sea ice. In countries and regions where sea ice occurs it is therefore of primary importance to monitor the sea ice regularly and produce ice forecasts to assist ship traffic, fisheries and other marine operations.

In the Northern Sea Route, the longest ice navigation route in the world, Russia has built up an extensive ice service to support the ship traffic. The service includes ice monitoring and forecasting as well as icebreaker escorting of cargo ships (Figure 2).

![Figure 2 Picture of Russian nuclear-powered icebreaker Sibiria leading a convoy of cargo vessels sailing through 2 m thick first-year (FY) ice in the Northern Sea Route.](image-url)
2 BRIEF HISTORY OF SEA ICE MONITORING

Sea ice observation from coastal stations and ships has a history of more than 100 years. Regular sea ice charting, however, using aircraft and satellites, has developed mostly after the Second World War. Aircraft surveys has been the main observation method, but the use of satellite data has developed gradually over the last three decades as a consequence of the instruments and observation techniques available from satellites.

The first satellite sensors providing views of the large-scale structure and motion of sea ice utilized visible and TIR channels such as those on board the early Nimbus, Tiros and Earth Resources and Technology Satellite (ERTS, later renamed Landsat). By the late 1960s, it was apparent that the sequential synoptic observations needed for sea ice and climate studies could not be acquired by satellite-borne visible and infrared (IR) sensors, which are limited to cloud-free and well-illuminated conditions. Sea ice exists in regions which are dark for several months and are frequently cloudy in the remaining months.\(^1\)

Therefore, it has been necessary to develop observation methods using microwaves which are able to penetrate clouds and are not dependent on light conditions. The first PMW remote sensing systems for satellites were launched on the Russian Cosmos 243 and Cosmos 384 in 1968 and 1970, respectively. In the USA, PMW technology was first used in remote sensing of sea ice during the early 1970s, when the Electrically Scanning Microwave Radiometer (ESMR) was flown on Nimbus-5 over the Arctic.\(^8\)

The period since 1970 has been one of great advancement in remote sensing of sea ice. After the ESMR period 1973–76, a more advanced satellite instrument, the scanning multichannel microwave radiometer (SMMR) was operated on Nimbus-7 for 9 years, from 1978 to 1987. This instrument provided the longest and first regular time series of global sea ice data. PMW observations have fairly coarse resolution (typically 30 km) and are more suitable for large-scale or global monitoring than for regional and local observations. AMW systems, such as side-looking radar (SLR) and synthetic aperture radar (SAR) were developed for aircraft surveillance and used in ice monitoring to provide detailed maps of the ice conditions, especially in areas of heavy ship traffic.

In 1978, Seasat was the first satellite which provided high-resolution SAR images of sea ice, but the satellite operated for only about 3 months. With spaceborne SAR data, which combines high spatial resolution with independence of cloud cover and light conditions, it is possible to observe sea ice with much better accuracy than visible, TIR and PMW methods. European Remote Sensing Satellite (ERS-1) represented a major milestone in satellite SAR remote sensing from 1991, because the satellite delivered tens of thousands of SAR images of sea ice from most ice covered regions in the world. The satellite SAR technology is being improved and SAR systems offered by the Canadian RADARSAT and the European Environmental Satellite (ENVISAT) satellites have wide swath, multimode and dual polarization. Other microwave systems such as scatterometer and SLR data have also shown promising results in sea ice observations.

In order for SAR and other satellite data to become central elements in ice observation, products useful for a wide range of users, interpretation techniques and algorithms must be improved and streamlined. The data products must be developed based on requirements from established users.

The status of sea ice monitoring can be summarized as follows: it is

- of national importance in countries whose coasts are ice-infested during the winter;
- of considerable economic importance in sea transportation;
- one of the most important and appropriate applications of satellite data with potential to increased use as new satellite data becomes available;
- an established and organized activity in many countries where sea ice has an impact on sea transportation;
- important for weather forecasting;
- important for climate change detection.

Use of satellite data in sea ice monitoring is developing steadily. The main aspects of this development are as follows:

- satellite methods using visible/IR data and PMW data are used operationally in many countries;
- the introduction of spaceborne SAR data represents a major milestone and improvement of ice monitoring quality;
- synergy with other data (aircraft, in situ) is essential for optimum extraction of ice information from satellite data;
- in many regions only satellites can provide data because aircraft and ships cannot cover the whole Arctic or Antarctic ice area;
- the market for sea ice data and related services is expected to grow because of increased activities and more focus on environmental issues in polar regions;
- considerable improvements of ice monitoring products and services are needed, which require more use of SAR data from satellites.
3 PHYSICAL PROPERTIES OF SEA ICE

3.1 Large-scale Ice Parameters Defined by the World Meteorological Organization

The definition of sea ice terminology has been standardized by the Sea Ice Working Group of the World Meteorological Organization (WMO), which established a nomenclature used by all institutions producing ice maps today. The main ice parameters, with examples of their values, are shown in Figure 3. The parameters are shown with symbols, such as the Egg code, in ice charts produced by operational ice centers.

The WMO nomenclature does not include the ice characteristics on smaller scale, i.e. on scales from centimeters to millimeters, which are important for several remote sensing methods. Limitations of the conventional ice codes from an ice navigation point of view are according to Lensu et al.

1. The classification of ice types is unnecessarily detailed for younger and thinner ice types which exist only for shorter periods of time in the freeze-up and early winter season. On the other hand, thicker, deformed and multiyear (MY) ice types are not characterized in as much detail as is needed. The classification should be proportional to the decrease in ship speed and increase in damage probability.
2. There is no quantitative reference to deformed ice types such as rafted ice, in spite of the fact that deformed ice can be predominant and several times thicker than level ice.
3. There is no quantitative reference to ice ridges or to their size and frequency of occurrence.
4. There is no reference to lead size, frequencies or orientations.
5. The relation of regional ice characteristics to what is experienced by an ice-going vessel is uncertain.
6. The codes cannot optimally use the information that is available from SAR images.
7. The terminology has no clear connection to geophysical ice models used in forecasting.

The main reason for these shortcomings is that the WMO nomenclature was defined in 1970, when
- no operative ice models existed;
- no high-resolution satellite data were available; and
- very few data on ice thickness, floe size and ridge distribution existed.

The code is clearly aimed to display visual and mainly qualitative observations, for example those made onboard a vessel. On the other hand, it is not feasible that a single ice code would satisfy all possible requirements. According to Lensu et al., a possible scenario for the future development of the ice codes could therefore be threefold:
- a geophysical code with theoretically sound concepts which can be related to satellite imagery and ice modeling;
- a navigational code which can be related to ship speed and damage probability; and
- an observational code as a further development of the Egg code.

3.2 Small-scale Ice Structure and Growth of Ice

A complete description of ice freezing and melting, the main physical processes responsible for the large seasonal variability in sea ice extent and volume, should start with a discussion of the structure of the H₂O molecule as it changes in the phase transition between solid and liquid. The fact that solid water (ice) has a lower density than liquid water, which is caused by this change in molecular structure, has the important implication that sea ice floats on top of the ocean. In this section, we shall describe only the most important physical properties very briefly, focusing on those which are important for remote sensing.

The basic physical parameters of sea ice are temperature, salinity, a crystal structure which incorporates brine and air, surface roughness, snow cover and the presence of liquid water on top of the ice, which frequently occur in the summer time when ice and snow melts at the ice surface.

Since sea ice is formed by freezing of salt water, there are important effects of the salt during the freezing process: some salt is released from the ice which is formed, and some ice is trapped in brine pockets of varying size. Ice formed during a winter season (FY ice) contains typically from 6 to 10‰ salt if the ice is formed from normal seawater with salinity of 35‰. The brine gradually drains from the upper part of the ice, causing MY ice to have a salinity of less than 1‰ in the surface layer, which is practically fresh water.

In the first stage of freezing, small ice crystals are formed at the surface, called frazil ice. As freezing continues and more ice crystals are formed, the crystals coagulate to form a soupy layer called greased ice. Frazil ice and grease ice dampen the short gravity waves at the sea surface, which has a significant impact on radar remote sensing of open ocean. An example of this dampening is shown in the photograph in Figure 4(a). If the freezing is allowed to continue without disturbance from surface waves, a weakly consolidated layer of elastic ice is formed. When this layer is less than 10 cm thick, it is called nilas. As it grows thicker and becomes less elastic, it is called gray ice (10–15 cm) and gray–white ice (15–30 cm). The process of brine drainage gradually replaces the brine pockets with voids of air which change the ice’s visual appearance from almost black nilas to bright grey and grey–white ice, which is significant in visual remote sensing of ice.

When wind and waves act on the ice freezing process, which is the normal situation in the marginal ice zone, the grease ice forms pancakes, which are small, rounded floes of elastic ice with a size from 30 cm to 3 m in diameter. The wave action causes continuous collisions between these floes, which generate raised rims which are typically 5–20 cm high (Figure 4b). The rims of the pancakes are

![Figure 4](attachment:image.png)

Figure 4 (a) Grease ice which dampens the short surface waves observable in the ice-free area on the left side of the image. (b) Pancake ice of different age. The smaller floes are 30–50 cm in diameter and 1–2 days old. The larger floes, 1–2 m in diameter, are several days old and composed of clusters of smaller pancakes. The photographs were taken by the Nansen Center during the Seasonal Ice Zone Experiment (SIZEX)’92 experiment.
efficient scatterers of radar waves used in remote sensing of sea ice.

In addition to the thermodynamic processes (freezing and melting) and the effects of the salt contents, there are important mechanical forces on the ice from winds and ocean currents, which cause the ice cover to converge or diverge. Convergence causes the formation of ridges, rafted ice and underwater keels, while divergence generates openings in the ice cover, called leads and polynyas. The leads and polynyas normally have open water or thin ice (nilas or grey ice) at the surface, which is detectable by most remote sensing methods if the resolution is good enough. The variability in surface roughness generated by ridging, rafting or other processes, such as pancake formation, is most readily observed by radar remote sensing data. The radar backscatter attains higher values in areas of high surface roughness than in areas of smooth ice surface.

In most areas, the sea ice is covered with layers of snow which have impact on the remote sensing signal, primarily the visual methods because the snow cover determines the surface albedo. Microwave remote sensing waves can penetrate snow unless the snow is wet or there are several layers of snow separated by thin ice. In regions with heavy snowfall, such as the East Greenland marginal zone, the ice can be loaded with wet heavy snow, which causes the whole ice floe to be flooded by seawater. When this occurs, the microwave remote sensing signals from the ice change. At the snow–ice interface, the snow is quickly recrystallized, which also has an effect on the radar return signal. The snow cover undergoes a characteristic seasonal cycle which affects the microwave remote sensing observations of sea ice (illustrated in Figure 5a–d). In the winter season, lasting 6–8 months from late autumn to the spring, defined by temperatures well below 0°C for both snow and ice, the snow cover is dry and practically transparent to microwaves. In late spring and early summer, when the temperature approaches 0°C, the snow becomes humid and eventually moist, which creates melt pools at the interface between the snow and ice. Continued warming during the summer period due to air temperatures above 0°C can melt away much of the snow and the top layer of the ice. In periods of most intense melting, a large part of the surface can be covered by melt pools (Figure 6a and b). For microwave remote sensing the amount of water at the surface is the most critical factor, whereas for optical remote sensing the variability of the surface albedo is most important. Typical values of the albedo are 0.8 for snow, 0.6 for dry ice and 0.2 for water-covered ice.

Figure 5 Snow and ice conditions on a MY floe which have impact on microwave remote sensing of sea ice. The four panels show characteristic conditions during (a) winter and early spring, (b) late spring, (c) early/midsummer, and (d) late summer.\(^{[41]}\)
The albedo is a key parameter controlling the incoming radiation, which determines the surface melt rate of snow and ice.

At the beginning of the cold season, all ice which survived the summer season becomes MY ice. The top layer (first meter) of a MY floe is harder, has lower salinity and is more optically transparent than a FY floe. The ridges of a MY floe are older, with more rounded and smoothed forms compared with the ridges of a FY floe. The most smooth areas are caused by refrozen pools covered with snow. The low salinity of the upper layer of MY ice makes it possible to discriminate FY ice from MY ice by microwave remote sensing during winter. This discrimination is not possible in the melt season, with water and wet snow on top of the ice. Another phenomenon of importance for remote sensing during winter time is the formation of frost-flowers on top of thin, high-saline ice which occur in cold weather. These crystals, which have dimensions of a few centimeters, cause very high backscatter of the AMW radar signal.

4 OVERVIEW OF SEA ICE REMOTE SENSING METHODS

4.1 Principal Methods, Instruments and Surface Characteristics

All remote sensing techniques for observation of the earth’s surface use electromagnetic (EM) radiation in the visible/near-infrared (VNIR), TIR and microwave bands of the EM spectrum. There are three principal measurement techniques applicable to ocean and sea ice observations:

1. measurement of the part of the incoming solar radiation that is reflected at the surface of the earth (VNIR remote sensing);
2. measurement of the thermal radiation from the surface (TIR and PMW remote sensing); and
3. measurement of the return signal from active source, especially microwave radar methods using several types of instruments which measure backscattered radiation from the surface.

The VNIR, TIR and the microwave channels utilize intervals of the EM spectrum with high atmospheric transmission, such as in the optical bands at 0.4–2.5, 3.5–4.0 and 10–13 µm. The EM waves in these intervals do not generally penetrate clouds, so remote sensing observations of the earth’s surface in these bands can only be done during cloud-free conditions. This is a severe limitation because sea ice occurs in regions where clouds are present most of the time, which inhibits regular observations of sea ice by satellite sensors operating in these bands. In the microwave area, at wavelengths above 0.3 cm, EM waves generally penetrate clouds, which makes it feasible to obtain regular, daily observations of sea ice (Figure 7a and b).

The most common satellite instrument used for measuring VNIR and TIR is the advanced very high-resolution radiometer (AVHRR), which provides images with a resolution of about 1 km in 4–5 different frequency channels. PMW radiometers, such as SSM/I, observe in a similar manner the emitted radiation in the microwave area in 4–5 channels and at different polarizations. The ground resolution varies in the range 15–150 km, depending on wavelength. AMW observations can be obtained by several types of instruments. The most common are SAR, SLR and scatterometers. The SAR instruments provide high-resolution images, with pixel size down to about 10 m, whereas the SLR provides medium-resolution images with a resolution of 1–2 km. Scatterometer data have coarser resolution, varying from 50 to about 10 km. The most common wavelengths for AMW instruments are 2.3 cm (X-band), 5.6 cm (C-band) and 23 cm (L-band).
The basic parameter observed by VNIR is the albedo, or alternatively the reflection coefficient. For TIR and PMW it is emitted energy as a function of surface temperature and emissivity, and for AMW it is a backscatter coefficient (also called normalized radar cross-section). These three basic parameters reflect many physical and chemical variables describing the ice surface within the field-of-view of the satellite instrument. The sea ice surface to be analyzed based on the measured albedo, energy or backscatter coefficient from a satellite sensor has three macroscopic components:

- open water outside the ice edge, in leads/polynyas and on top of the ice in summer;
- ice with varying amount of salt water intrusions (salt pockets);
- snow on top of the ice.

The following properties of the macroscopic components have an impact on the remote sensing measurements:
- the percentage and distribution of the three components;
- the temperature of the components;
- the salinity of the components and the distribution of salt intrusions in the ice;
- the crystal structure of the ice and the snow;
- the occurrence of layers (e.g. snow–ice) and rough surfaces (e.g. floes, ridges, frost-flowers).

In addition, there are variables defined by the remote sensing instrument which also have significant impact on the measurements:
- the frequency (wavelength) of the radiation;
- the angle of incidence for the radiation;
- the polarization of the radiation if different from vertical.

4.2 Electromagnetic Properties of the Macroscopic Components

The most important EM properties of any surface are reflection and emission. The latter, expressed by a dimensionless coefficient called emissivity, can be computed from the complex dielectric constant (or the relative permittivity), $e = e' - ie''$, which characterizes the electrical properties of the media; $e'$ is referred to as the dielectric constant and $e''$ as the dielectric loss factor. Alternatively, $e$ can be estimated from the complex index of refraction, $n$, where $n^2 = e$. The reflection coefficient $r$ is defined according to Equation (1):

$$r = \frac{n - 1}{n + 1}$$

Figure 7 (a) EM spectrum showing the bands used in remote sensing, together with the operating area for some sensors. (b) Atmospheric transmission of the EM spectrum.
The dielectric constant, together with the surface roughness of the target, determine the emissivity. At microwave frequencies, the emitted energy, called brightness temperature, $T_b$, is a product of surface temperature, $T_s$, and the emissivity.

### 4.2.1 Open Water

Observation of open water is necessary as a reference for identification of sea ice, especially for the detection of the ice edge and areas of new ice formation. Within sea ice, open water can occur in leads and polynyas, and it is important to know if there is open water or thin ice in these areas. Examples of reflection coefficients for calm, pure water at two different wavelengths and normal incidence angle, using Equation (1) are as follows:

- For visible radiation at 0.55 μm, $n = 1.33$, which gives $r = 0.02$;
- For TIR radiation at 11 μm, $n = 1.20$, which gives $r = 0.008$.

The low reflection coefficients show that water is dark at visible and almost a blackbody at TIR wavelengths. For microwave remote sensing, water temperature and salinity are also important. Equations for computing reflection/emission coefficients from the dielectric constant can be found in Strogyn.\(^{(12)}\) Examples of reflection and emission coefficients, at normal incidence, 273 K and 35‰ salinity are as follows:

- For microwave radiation at 10 GHz, $e = 38 - 41i$;
- For TIR radiation at 11 μm, $n = 1.20$, which gives $r = 0.008$.

Seawater is therefore a graybody at microwave frequencies, with emissivity as a function of frequency.

### 4.2.2 Microwave Electrical Properties of Ice

In the microwave wavelength region and for the physical temperatures encountered, the Rayleigh–Jeans approximation of the Planck radiation law pertains. The radiated power, usually expressed as brightness temperature, $T_b$, is therefore proportional to the physical temperature, $T_s$, at the surface. Most real objects emit only a fraction of the radiation that a perfect emitter would do at the same physical temperature. This fraction defines the emissivity of the object as $T_b/T_s$. Spatial variations in $T_b$ observed over the surface of the earth are due primarily to variations in the emissivity of the surface material and secondarily to variations in temperature.

The value of the dielectric constant $e'$ for freshwater ice has been measured as 3.17 at 10 GHz and varies little with frequency.\(^{(13)}\) For saline FY ice, $e'$ is higher and strongly dependent on both temperature and salinity of the ice. Only a small amount of brine will alter the dielectric constant of the ice, owing to the high value of $e$ for salt water. A brine volume of 4‰ was found to give apparent dielectric constant of about 4.5. Lower temperatures will reduce the dielectric constant.

For sea ice, the dielectric constant $e'$ is relatively constant with frequency above 1 MHz, but $e''$ is not. There is a minimum in $e''$ at 3–8 GHz, with higher values for lower and higher frequencies. For FY ice at 283 K and 8‰ salinity, the minimum $e''$ is approximately 0.3. As the temperature decreases, $e''$ will increase because precipitated salt will go back into solution. Furthermore, $e''$ will decrease with decreasing salt content. MY ice has a lower $e''$ than FY ice and its temperature dependence is weaker. Hence microwave radiation penetrates deeper into MY ice than FY ice.

Empirical relations have been established for the dielectric constant and thus the emissivity for sea ice at different microwave frequencies (Figure 8a and b). For example, the emissivity of seawater at 19 GHz and vertical incidence is about 0.44 compared with 0.92 for FY ice and 0.84 for MY ice. In contrast to water, it is not only the temperature, salinity, incidence angle and polarization which determine the emissivity of sea ice; the structure of the crystals and of the brine pockets – different for various ice types and ice ages – are also important.

### 4.2.3 Microwave Electrical Properties of Snow

There is a large difference in electrical properties between dry snow and wet snow with high liquid water fraction. Snow without salt can be considered dry in temperatures below $-1^\circ$C. Wet snow has a high $e''$, with correspondingly high absorption and emission. In summer, therefore, microwaves will only sense the top layer of the snow cover on the ice.

In winter, dry snow is almost transparent, with very small $e''$. However, the bottom snow layer on FY ice can contain salt, and with 4% salt the effect is to double the value of $e''$ from the value of 0.3 for pure ice. The dielectric constant $e'$, which is independent of frequency, is only weakly dependent on temperature, and increases with increase in snow density. For a density of 0.2 g cm$^{-3}$, $e'$ has a value of approximately 1.3.

### 4.3 Basic Remote Sensing Parameters

For a radiometer in the TIR or the microwave region, electrical and thermal properties of the surface will largely determine the basic parameter measured by the sensor. For a visual radiometer and in particular for a radar, the geometrical structure of the surface is often the
4.3.1 Albedo

In the visual part of the spectrum, the albedo (or the reflection coefficient) is measured as a value between 0 (total absorption of the sunlight) and 1 (total diffuse reflection of the sunlight). Of the macroscopic sea ice components, new snow has the highest values of about 0.8. As the snow ages, the albedo decreases to values equal to dry old ice of 0.6 or lower. For very old and wet surfaces of ice and snow, the value can be as low as 0.2. Open water has an even lower albedo, varying somewhat with incidence angles and wind. The vertical reflection coefficient of calm pure water is only about 0.02.

For snow and ice, the visual albedo decreases slowly with increasing wavelength. In the near-IR region the decrease is more rapid for most snow and ice types, reaching very low values below 0.1 for wavelengths over 1.5–2.0 μm. This low albedo can be utilized in the discrimination of snow/ice from clouds. This is a major problem in the visual part of the spectrum where snow and clouds often show a similar signal.

4.3.2 Surface Temperature

In the TIR part of the spectrum, the surface signal expressed as the radiance obtained by remote sensing can be used as input to the Planck equation of radiation to find the surface temperature \( T_s \) if the emissivity \( e \) of the surface is known. For water, the value of \( e \) in the most used thermal spectral band of 10–12 μm is very high and stable, about 0.99, and accurate measurement (to 0.1–0.2 K) of the water surface skin temperature can be made. Snow and ice also have high emissivity in this region (values not well known) and approximate temperature measurements (to 1–2 K) of the upper layer can be made.

4.3.3 Brightness Temperature

As discussed above, the brightness temperature \( T_b \) provides the measurement of the PMW emission from the surface. The brightness temperature is defined by the real surface temperature \( T_s \) and the emissivity \( e \) by the relation \( T_b = T_s e \). Depending on the application, various methods can be applied to separate the two variables \( e \) and \( T_s \). For the most frequently used frequencies between about 6 and 90 GHz, the emissivity of both ice and water show large variations. Whereas \( e \) for calm water can be calculated fairly accurately from the electric properties, the value and variation of \( e \) for the various forms of ice and snow are less accurately known, and therefore often have to be measured empirically. PMW instruments typically have a very low-resolution cell in which many different components of snow, ice and water are present. Multifrequency measurements are widely applied in algorithms for determining the relative coverage (concentration) of the sea ice components and possibly also of other parameters.

4.3.4 Radar Backscatter Coefficient

For AMW systems, the most important parameter is the backscatter coefficient \( \sigma_0 \), which expresses a measure of the energy scattered towards the source of the radiation, at a scattering angle of 180°. The backscatter coefficient and other related parameters are discussed further in section 5 which deals with imaging radar systems.
5 IMAGING RADAR SYSTEMS

5.1 Basic Properties of Imaging Radar Systems

Imaging radars are used for the detection and ranging of objects and features at the earth’s surface. Imaging radars provide their own source of illumination in the microwave portion of the EM spectrum, at wavelengths of the order of 10,000 times longer than those in the visible part of the spectrum. Because of this, radars can operate independently of solar illumination and can penetrate clouds and precipitation. An imaging radar sends out energy in the form of an EM wave which strikes an object, causing it to be reflected back. The radar system senses the intensity of the reflected wave and at the same time measures the time taken for a round trip. Radar systems are different from more conventional visible and TIR systems in the following ways:

- radar is extremely sensitive to the surface roughness of the area being imaged;
- radar does not detect the visible color of the surface, but detects the moisture (or lack of) and electrical properties of the surface;
- radar systems record the phase and polarization characteristics of the reflected microwave pulse;
- radar produces images with speckle due to the coherent nature of the system;
- radar produces images with certain geometrical distortions, such as slant range geometry, image layover and shadowing; and
- radar is sensitive to the motion of objects in the imaged area.

A further description of an imaging radar system requires the definition of a set of variables that will lead to the remote sensing parameters used in the observation of sea ice and other surface features by spaceborne radar systems. Extensive descriptions of radar remote sensing principles have been published by Ulaby et al.\textsuperscript{14,15} The following review is based on the radar remote sensing manual for the polar oceans by Shuchman et al.\textsuperscript{16}

5.2 Some Important Parameters and Properties

The overall geometry of the ERS SAR systems is shown in Figure 9. The ERS SAR looks to the right of the orbit, covering the area between 244 and 344 km away from the nadir, which is the ground projection of the satellite orbit. The two main orientations are called azimuth (along the satellite orbit) and range (the look-direction of the SAR, perpendicular to the orbit). Range is also defined more precisely as a distance. The measurements of travel time of the reflected microwaves are readily converted to distance, which in radar usage is always called range, defined according to Equation (2):

\[
R = \frac{c\tau}{2}
\]  

(2)

where \(c\) is the speed of light and \(\tau\) is the travel time of the radar pulse. Range is also used to define the location of an object in the cross-track direction, which is perpendicular to the satellite flight direction (along track), called azimuth. In imaging theory, resolution of a radar system is defined as the radar’s ability to discriminate between two point targets, observable as bright spots in a particular image. Two different principles determine the resolution of a radar system: azimuth resolution is defined by the beamwidth \(\beta\) of the radar, which is the angle by which the radar beam expands, and is a function of the antenna size and range. The location of a reflecting object is somewhere within the cross-hatched area in Figure 10, which is the area on the surface illuminated by a radar pulse. The along-track dimension, or azimuth resolution \(r_a\), is defined according to Equation (3):

\[
r_a = R\beta
\]  

(3)

The beamwidth of the radar is a function of the antenna length, with a larger antenna producing a narrower beam. For real aperture radars, such as SLRs, the only way to obtain fine azimuth resolution is to have a very short range or a very large antenna. SARs overcome this problem by utilizing the along-track motion of the satellite (or aircraft) to produce a very large antenna.

Figure 9 Geometry of the SAR system of the ERS-1/2 satellites.
The range resolution \( r_r \) of a radar system is given by Equation (4):

\[
r_r = \frac{c t_p}{2}
\]

where \( t_p \) is the duration of the transmitted radar pulse and \( c \) is speed of light. Range resolution is the distance that two objects must be separated to be detected at two unique ranges.

Imaging radars operate at microwave frequencies between 400 MHz and 35.2 GHz, corresponding to wavelengths between 62 and 0.85 cm. Radar frequencies are identified by letter designations, the most commonly used being the K-band (30 GHz, 1 cm), X-band (9.4 GHz, 3.2 cm), C-band (5.3 GHz, 5.7 cm), L-band (1.25 GHz, 23.5 cm) and P-band (450 MHz, 62 cm). At these wavelengths the EM waves are not appreciably attenuated by clouds, precipitation or the earth’s atmosphere. Therefore, good-quality radar images can be obtained during all kinds of weather and light conditions. Another characteristic of imaging radar systems is polarization, which is defined as the direction of the electric vector is perpendicular to an EM wave. The electric vector is the plane in which the EM energy is transmitted. Visible light is unpolarized because the direction of the electric vector is randomly distributed. For radar systems it is common to emit pulses which are either horizontally (H) or vertically (V) polarized. The radar antenna can receive either the horizontally or vertically oriented return signals, or both.

In contrast to visible and IR remote sensing, radar remote sensing is extremely sensitive to the surface roughness. For smooth surfaces, there is near specular reflection of the radar waves, and little energy is reflected back to the radar. As the surface becomes rougher, the radar wavelengths interact with the surface in a way which causes diffuse reflection (Figure 11a–c). The amount of roughness controls the distribution of the reflected energy, and thus the intensity in the radar image. The wavelength and incidence angle of the radar wave determine the extent to which a surface is rough or not. There is a criterion for this [Equation 5]:

\[
\Delta h \cos q_1 > \frac{\lambda}{8}
\]

where \( \Delta h \) is the vertical scale of the surface roughness, \( q_1 \) is the incidence angle and \( \lambda \) is wavelength.

### 5.3 The Radar Equation

All radar measurements can be described by a basic equation which relates power, distance, reflectivity and antenna characteristics, which can be formulated as Equation (6):

\[
P_R = \frac{P_t G \sigma A}{(4\pi)^2 R^2}
\]

where \( P_R \) is power received, \( P_t \) is power transmitted, \( G \) is the gain of the antenna, \( \sigma \) is the radar cross-section and \( A \) is antenna area. \( A \) can also be expressed as \( \lambda^2 G/4\pi \),
which is used to rewrite Equation (6) as a product of four terms [Equation 7]:

\[ P_R = \frac{P_i}{4\pi R^2} \frac{G}{4\pi R^2} \sigma A \]  \hspace{1cm} (1) \hspace{1cm} (2) \hspace{1cm} (3) \hspace{1cm} (4)

The energy of the outward propagating wave, which is spherically expanding, is given by term (1). This spherically expanding wave is focused down to an angular expanding wave. The focused energy impinges on an object which has a radar cross-section \( \sigma \), defined as the equivalent of a perfectly reflecting object of a given area which reflects isotropically (spherically), as shown by term (3). Finally, the antenna area, \( A \), term (4), intercepts a portion of the reflected wave so that the portion of the flux produces the power received by the antenna.

The basic radar return equation is general; it can be applied to any object of any shape or composition. For imaging over areas of terrain or ocean, a reflection coefficient is defined, \( \sigma_0 \), which is the radar cross-section, \( \sigma \), per unit area. The radar Equation (6) can then be expressed as Equation (8):

\[ P_R = \frac{\lambda^2}{(4\pi)^3} \frac{P_i G^2 \sigma_0}{R^4} dA \]  \hspace{1cm} (8)

The averaged received power for a radar can then be determined by examining the integral radar equation for distributed targets. The radar scattering coefficient, \( \sigma_0 \), also called the backscatter coefficient, is important because it is an absolute measure of scattering behavior. It is a function of frequency, incidence angle, polarization and the scattering characteristics of the illuminated area. It is defined to be unity for a surface of small metal balls which exhibit ideal diffuse scattering without impacts of varying incidence angles. The backscatter from various

![Graphs showing backscattering coefficient \( \sigma_0 \) as a function of frequency and incidence angle for two major ice types.](image)

**Figure 12** Backscattering coefficient \( \sigma_0 \) as a function of (a) and (b) frequency and (c) incidence angle for two major ice types.\(^{(17)}\)
sea ice surfaces is generally much smaller than unity at the most used incidence angles ($20°$–$50°$). Examples of the dependence of the backscatter coefficient on frequency and incidence angles for different ice types are shown in Figure 12(a–c). In section 7, examples of measurements of $\sigma_0$ by SAR for different ice types and surface conditions will be discussed.

6 CASE STUDY OF PASSIVE MICROWAVE REMOTE SENSING OF SEA ICE

6.1 Observation of Brightness Temperature

As discussed in section 4.2.1, the microwave brightness temperature $T_b$ of the earth’s surface depends on the electrical properties of the surface, embodied in its emissivity $\varepsilon$ and the physical temperature of the radiating portion of the surface $T_s$. This may be expressed by the following relation in terms of the wavelength $\lambda$ and polarization $p$:

$$T_b[\lambda, p] = \varepsilon[\lambda, p]T_s$$  \hspace{1cm} (9)

This relationship is true only for $\varepsilon$ and $T_s$ independent of depth, a typical assumption for sea ice.$^{(18)}$ The radiative transfer equation is the basis for the development of algorithms that convert the satellite radiance data into geophysical parameters. The microwave radiances received by the satellite are composed of various contributions from the earth, atmosphere and space and are illustrated schematically in Figure 13. The radiation received by the satellite, which is a function of wavelength and polarization as shown in Equation (9), can be expressed by Equation (10):

$$T_b = \varepsilon T_s e^{-\tau} + T_{up} + (1 - \varepsilon)T_{down} e^{-\tau} + (1 - \varepsilon)T_{sp} e^{-2\tau}$$  \hspace{1cm} (10)

![Figure 13](image-url) The main components of the brightness temperatures, observed by PMW radiometer in a satellite, are expressed by four terms in the radiative transfer equation.$^{(18)}$
where $T_b$, $T_s$ and $e$ are as before, $e^{-t}$ represents atmospheric absorption, $T_{up}$ is the atmospheric upwelling radiation, $T_{down}$ is the atmospheric downwelling component and $T_{sp}$ is the cosmic background component, as illustrated in Figure 13\(^{(19)}\).

### 6.2 Algorithms for Retrieval of Ice Parameters

There are several algorithms for estimation of sea ice concentration from brightness temperature observed in several channels and both polarizations\(^{(18)}\). An example of such an algorithm is NORSEX-85H, which is an extension of the NORSEX algorithm developed by Svendsen et al\(^{(2)}\) based on the SMMR data available from 1978 to 1987; 85H means that the extended version takes advantage of the improved spatial resolution of the 85-GHz channels provided by the SSM/I system which is currently in operation.

The basic algorithm was developed after the NORSEX marginal ice zone experiment near Svalbard in 1979 conducted by the NORSEX Group\(^{(20)}\). The algorithm computes area concentration of total ice and two ice types: MY ice and FY ice. Two channels are used: 18 GHz vertical polarization and 37 GHz vertical polarization. Only vertical polarization is used, since it was found to be significantly less sensitive to surface structure (snow layering, snow density, roughness) than horizontal polarization.

The ice emissivities and the atmospheric opacities used in the algorithm were basically measured during the NORSEX’79 experiment. Ocean water emissivities are theoretical values\(^{(12)}\). The brightness temperature of the surface is modeled as the linear combination of the area fraction of water, FY ice and MY ice in the field-of-view. A simple atmospheric model with surface air temperature as a parameter is used to convert satellite-observed brightness temperature to surface-observed brightness temperature.

The NORSEX algorithm requires that input brightness values are adjusted by a few degrees K to give 100% water over calm, open polar water. These adjustments are made based on a few suitable scenes where the state for the atmosphere and the surface is known, and thereafter kept largely unchanged. Adjustments are different for SMMR and SSM/I.

A rough estimate of the average surface air temperature over 100% pack-ice from climatological data is used as input for each scene. The NORSEX algorithm output is % water, % FY ice and % MY ice with a spatial resolution of approximately 60 km for SSM/I; 60 km is the resolution of the 19 GHz channel.

![Figure 14](image.png)

**Figure 14** Example of ice concentration map derived from SSM/I data in the Svalbard area. Isolines for 20, 50 and 80% ice concentration are drawn. Open water is areas with less than 20% ice.
The 85 GHz channel, H polarization (85H), is very sensitive to the difference between water and FY ice and to the atmosphere. This channel is used to sharpen the ice–water boundary in the following way.

The 85H is spatially lowpass filtered to the 18V/37V algorithm resolution of 60 km. Concentration values are then multiplied with the ratio of the 85H signal to the lowpass-filtered 85H signal. This results in an image with a spatial resolution of 15–20 km, given by the 85H signal, and with ice concentration values given primarily by the basic NORSEX algorithm.

The NORSEX-85H algorithm was developed for use under the SIZEX’92 experiments in the Greenland and Barents Sea. \cite{21} The ice edge defined by the 30–50% contour lines compares favorably with the ice–water boundary seen in near-simultaneous SAR images both under SIZEX’92 and later field experiments.

### 6.3 Example of Ice Analysis from Special Sensor Microwave Imager Data

The most common ice analysis using SSM/I data is to calculate total ice concentration by an algorithm as described in the previous section. An example of ice concentration maps is shown in Figure 14. The data were received on file in the form of geolocated brightness temperatures, and the required channels were resampled on to a raster with 6-km spacing. On this raster, ice was computed using the NORSEX algorithm and thereafter sharpened by using the channel 85H signal as explained above. Then a contouring algorithm was applied to plot the 20%, 50%, and 80% isolines for concentration. The map was produced on the same day as the satellite measurements were obtained, 27 September 1997, by transferring data from the SSM/I data distribution service in the USA. The SSM/I data are used for daily ice monitoring all over the world.

The most direct, quantitative means to study the global sea ice cover are satellite PMW remote sensors. Sea ice time series derived from multichannel PMW data are among the longest continuous satellite-derived geophysical records, extending over two decades. The Nimbus-7 SMMR provided data from 1978 to 1987, and the follow-up SSM/I onboard Defense Meteorological Satellite Program (DMSP) satellites have provided data since 1987. The 25 × 25 km gridded data sets are issued by the National Snow and Ice Data Center (USA). The brightness temperature data are used to calculate total ice concentration (the percentage of ice-covered ocean within an image pixel), from which total ice area (the area of ice-covered ocean) and total ice extent (the area within the ice–ocean margin) are derived.

Analysis of SMMR and SSM/I records taken separately revealed a greater reduction in Arctic sea ice area and extent during the SSM/I period. The decreases from 1987 to 1994 were ca. 4% per decade compared with ca. 2.5% per decade from 1978 to 1987, \cite{4} with no significant trends found in the Antarctic. Since then, merged SMMR–SSM/I time series have been produced and analyzed, establishing the trends more firmly. Bjergo et al. \cite{22} established the trend in Arctic ice area and extent (1978–95) to be about −0.3 × 10^6 km^2 per decade (Figure 15a and b), corresponding to ca. 3% per decade, with no significant change in the Antarctic. The 3% per decade decrease in the Arctic ice extent (1978–97) was subsequently corroborated in a separate analysis \cite{23} that also confirmed the hemispheric asymmetry seen earlier. \cite{4, 22} Cavalieri et al. \cite{23} found a slight (ca. 1.5%) increase in the Antarctic, which may be considered significant. The hemispheric ice covers fluctuate quasi-periodically, with predominant periods between 3 and 5 years, although their variability is apparently not correlated. \cite{23}

The capability to monitor interannual variations in MY ice area from SMMR and SSM/I data has recently been exploited using winter data, when FY and MY ice signatures permit their distinction. The analysis revealed a relatively large (ca. 7% per decade) reduction in the MY ice area from 1978 to 1998 (Figure 15c), compared with ca. 2% per decade decrease in the total ice area in winter. This finding is supported by an SMMR–SSM/I data analysis that found an 8% increase (5.3 days) in the length of the sea ice melt season in the Arctic from 1978 to 1996. \cite{24} It is also corroborated by spatially and temporally fragmentary observations (from submarine sonar transects) of ice thickness decreases, and also oceanographic data that have revealed changes in Arctic water masses since the 1970s that are reasoned to stem from a substantial (ca. 2 m) melting of perennial MY ice. If this trend were to continue, it could eventually lead to a markedly different sea ice regime in the Arctic, altering heat and mass exchanges and also ocean stratification.

### 7 CASE STUDY OF ACTIVE MICROWAVE REMOTE SENSING OF SEA ICE

The most important AMW remote sensing instrument for ice monitoring is the SAR, which provides high-resolution images of the ice surface. In this section we present some results of the SIZEX experiment, which was an ERS-1 SAR ice validation experiment in the Barents Sea in March 1992. \cite{21}

#### 7.1 General Interaction Between Synthetic Aperture Radar and Sea Ice

The radar backscatter from sea ice is highly dependent on physical ice properties such as salinity content,
Figure 15 Time series of Arctic ice area derived from SMMR and SSM/I satellite PMW data: (a) monthly mean and (b) anomalies in ice area in 1978–95 where the linear regression indicates a ca. 31 000 km² yr⁻¹ decrease, corresponding to ca. 3% per decade. (c) Fraction of MY (i.e. having survived the summer melt) sea ice area in winter (November–March), 1978–98, where the linear regression indicates a ca. 30 000 km² yr⁻¹ decrease, corresponding to ca. 7% per decade.
During the SIZEX’92 experiment some of these problems were studied in more detail.

### 7.2 Synthetic Aperture Radar Data Characteristics

During SIZEX’92, C-band ERS-1 SAR images with VV polarization were downlinked and processed at Tromsø Satellite Station and distributed to the Nansen Center for further analysis in addition to real-time use during the field experiment. SAR backscatter values from several ice types and open water conditions were analyzed during the experiment. Each image was averaged from 16 × 20 m to 100 × 100 m pixels, thereby removing much of the speckle noise. The images were then normalized to an incidence angle of 23° (in the center of the swath) by applying antenna pattern range spread and incidence angle corrections as described by the European Space Agency (ESA). Finally, the pixels in the images were calibrated to $\sigma_0$ backscatter values by the relation $\sigma_0 = 20 \log V - 46.9$, where $V$ is the digital value of the images analyzed at the Nansen Center. The lowest backscatter observed in the images had values of $V = 14$ (grease ice), and this was assumed to correspond to the noise floor of $-24$ dB. The accuracy of this calibration is estimated to be 1–2 dB.

### 7.3 Joint Analysis of Synthetic Aperture Radar Images and In Situ Measurements

The primary in situ measurements were profiles of snow and ice parameters taken at several sites from ships and helicopter. A total of 21 sites were investigated during the SIZEX experiment from March 2 to 11, 1992. At each site, several ice cores were drilled to obtain some spatial statistics of the ice parameters. The ice cores were analyzed for temperature, salinity, density and brine volume. Ice type was identified, ice thickness was measured and surface roughness was characterized. Snow thickness, temperature, grain type, grain size, density and layer description were also obtained at each site. An example of a SAR scene extending from open water to the interior of the ice pack is shown in Figure 17(a). From the SAR images and the in situ observations, the ice conditions in this part of the Barents Sea could be divided into three zones, reflecting different physical processes. In the following discussion, each of these zones, which are denoted A, B and C, are described in terms of their SAR signatures. Results of classification of the SAR images into six classes are shown in Figure 17(b).

#### 7.3.1 Zone A: the Interior of the Ice Pack

In the upper left part of the SAR image in Figure 17(a) many MY floes were found about 100 km into the ice pack. The backscatter value of these floes were typically $-9.0 ± 1.5$ dB. Between the MY floes, areas of undeformed FY ice typically 2–3 m thick were observed. This ice had backscatter values from $-10$ to $-13$ dB. Refrozen leads with smooth thin ice had the lowest backscatter values, between $-19$ and $-13$ dB. Ridges and leads with open water were found to have variable and higher backscatter, above $-8$ dB. In the interior of the ice pack the ERS-1 SAR demonstrated its ability to discriminate between (a) young ice in refrozen leads, (b) MY ice in large floes, (c) rubble fields/ridges and (d) smooth FY ice, using simple thresholding of backscatter values.
7.3 Zone B: the Small Floe Area

This zone is characterized by small floes, typically 10–100 m in size, which have been broken up by surface waves penetrating from the open ocean into the ice pack. The width of the zone depends on the intensity of the wave field in the preceding days. During the SIZEX experiment the zone was 20–30 km wide and was clearly identified in the SAR images as a more uniform zone between open ocean and the interior of the ice pack (Figure 17a). The dominant ice type is rough FY ice 2–3 m thick with backscatter values ranging from −10 to −6.5 dB. These values are significantly higher than for the undeformed FY ice in zone A, owing to the increased surface roughness. This surface roughness is caused by the edges and ridges of the numerous small floes which cannot be identified in the SAR images. During the experiment the ice concentration was generally high (>95%). The open water or thin ice areas between the floes was in the range 1–10 m, which could not be observed in the SAR images.

MY floes, which drift southwards with the East Spitzbergen Current, could also occur in this zone. Similarly to the FY floes, the MY floes tended to break up, owing to the wave field. The SAR signature of small MY floes was similar to that of surrounding FY floes. Drifting icebergs with a horizontal scale of 100 m and a draft of 5–8 m were frequently observed in the zone, but their SAR signature even in full-resolution images was diffuse. Reliable observations of these icebergs could not be made by the ERS-1 SAR.

7.3.3 Zone C: the Area of Ice Formation

Most of the ice in the Barents Sea is formed locally as the ice edge advances southwards during the freezing season. In the experiment, the areas of ice formation were mapped by SAR images and documented by in situ observations. The first stage in ice formation is grease ice, which dampens out the short surface waves and causes low radar return signals. This ice had the lowest backscatter of all ice types, ranging from −24 to −14 dB. After 1–2 days of freezing, the grease ice starts to form pancake ice with characteristic edges which causes a high radar return, typically above −7.0 dB. As the pancake ice grows thicker during the winter it forms 1–2 m thick FY ice. The ice in this zone is constantly exposed to surface waves and is therefore characterized by a rough surface. Grease ice and calm water (wind speed below 3 m s⁻¹) can have overlapping backscatter values which make the interpretation of the SAR images ambiguous; however, no wind speeds below 3 m s⁻¹ were observed in the experiment. Open water in the SAR images had higher backscatter than any of the observed ice types, from −4.5 to −3.0 dB. The backscatter values for the most important ice types in the Barents Sea are summarized in Figure 18.

7.4 Summer Conditions

The classification into three zones suggested for winter conditions would not be valid in the summer, because the interaction between radar microwaves and the ice surface is completely different from winter conditions owing to the different temperature. Zone C with ice formation would be absent. Zones A and B would be detectable, but the discrimination between different ice types becomes less significant. Owing to wet snow and melt water on top of the ice, the SAR backscatter values from MY floes is reduced compared with the winter situation and becomes similar to the signature for FY ice. It is therefore difficult to separate the two ice types based solely on backscatter levels. Thin ice types such as grease ice, pancake ice and young ice are usually not found in the summer.
7.5 Conclusion from the Synthetic Aperture Radar Ice Classification Study

In the SIZEX'92 experiment, ERS-1 SAR scenes of all the major ice types in the Barents Sea were analyzed for winter conditions. These included:

- 3–4 m thick MY ice floes which originate from the Arctic Ocean north of Svalbard;
- refrozen leads with smooth thin ice;
- consolidated FY ice 2–3 m thick which is formed between MY floes in the interior of the ice pack during the present winter season;
- rough ice in leads, ridges and rubble fields;
- FY ice 2–3 m thick in a 20–30 km wide zone inside the ice edge broken up in typically 10–50 m large floes due to wave action;
- new ice formed outside the ice edge (grease ice and pancake ice).

The most difficult factor which influences the SAR ice classification and ice concentration algorithms is the variable backscatter from open water due to the wind speed. Ice classification algorithms have been applied to the SAR images from the SIZEX experiment, and the results from use of the Wackerman algorithm are shown in Figure 17(b). Such classifications will normally result in ambiguities, because different ice types can have similar SAR signatures. Also, open water can have a similar signature to some of the ice types, in particular pancake ice and ice with rough surface. In order to improve the algorithm for ice type determination and thus also for the ice edge detection and ice concentration estimation, it is necessary to know the open water signature as a function of wind speed. The wind speed can thus be used as an input parameter in the algorithms.

The main result of the SIZEX program and other SAR ice investigations is an improved understanding of ice processes and their signatures in SAR images. All the previous SAR ice studies have contributed to the establishment of look-up tables, such as in Figure 18, for many ice types at different seasons. Although there are many phenomena and features observable in SAR images which remain to be explained, the general knowledge of SAR ice signatures is fairly well established.

8 FUTURE PERSPECTIVES ON SEA ICE REMOTE SENSING

Sea ice remote sensing by use of satellites is expected to become increasingly important both for climate...
monitoring and for process studies investigating the interaction between ocean and atmosphere. After the SIZEX experiment, there have been developments towards operational use of satellite SAR data in ice monitoring in many countries. The ESAs ERS program has been very instrumental in developing SAR ice monitoring methods, including algorithm development, validation and user demonstrations. From 1996, the Canadian RADARSAT has provided SAR images covering up to 500 km wide swaths which are very useful in operational ice monitoring. The ice centers in the USA and Canada use RADARSAT SAR data as the main source of information, while, in Europe, Finland, Sweden and Denmark have introduced these data in regular ice monitoring service in the Baltic Sea and Greenland waters.

Several new satellites, carrying SAR, scatterometer, PMW radiometers and other relevant instruments, will have an increasingly important role in ice monitoring. The next satellite of interest will be ENVISAT, scheduled for launch in 2001, which will have Advanced Synthetic Aperture Radar (ASAR), a new SAR with the possibility of obtaining data in several polarizations and at different resolutions and incidence angles. Several other SAR satellites, which will have ice monitoring as one of their tasks, are planned for the next decade.

Semiarid Land Assessment: Monitoring Dry Ecosystems with Remote Sensing

Joachim Hill
University of Trier, Trier, Germany

1 Introduction

Dryland areas cover approximately one-third of the continental surface of the earth. In particular the semiarid ecosystems provide important land resources for adapted agricultural production and grazing systems. While often considered areas at risk in the context of global climatic change and worldwide desertification dynamics, the importance of thoroughly monitoring the state of the environment in these areas has long been recognized. However, with regard to the spatial extension but, at the same time, limited accessibility of dryland systems, it becomes obvious that terrestrial observation alone is hardly able to cope with this task. Remote sensing with air- or space-borne sensor systems provides a comprehensive spatial coverage, is intrinsically synoptic and collects objective, repetitive data, and is thus ideally suited for monitoring environmentally sensitive areas. The major problem associated with its use is to interpret quantitatively a measured signal that has interacted with remote objects in terms of the properties of these objects.

Since most semiarid lands are characterized by frequently cloud-free atmospheres it is obvious that remote sensing systems operating in the optical range of the wavelength spectrum are and have been used predominantly. Besides airborne systems for individual surveys on local to regional scales, several geostationary and polar-orbiting satellites [e.g. METEOSAT GOES, National Oceanographic and Atmospheric Administration (NOAA) (of the USA) advanced very high resolution radiometer
Besides referring to general characteristics such as limited water resources, highly irregular rainfall patterns, incomplete plant cover with mostly xeromorphic species, and specific risks for agricultural use, the definition of drylands is a matter of distinct parameters. In 1977, UNESCO published its synthetic map of the distribution of drylands (Figure 1) where the degree of aridity is defined by the bioclimatic index \( P/PET \) [ratio between total annual precipitation (P) and potential average evapotranspiration (PET) (i.e. quantity of water lost by evaporation directly from the soil and by transpiration of a plant cover) from measurements at 1600 meteorological stations]. Four grades of aridity are distinguished (see also Mainguet):

- **Hyperarid**: \( P/PET < 0.03 \), the average rainfall is 10–50 mm a\(^{-1}\) and the interannual coefficient of variability exceeds 40% (a zone corresponding to extreme deserts without vegetation, except for some ephemerals and xerophytic bushes in the beds of wadis).
- **Arid**: \( 0.03 < P/PET < 0.20 \), the average rainfall is 50–100 mm a\(^{-1}\) and the interannual coefficient of variability is 30–40% (barren areas or areas covered by sparse vegetation of perennial and annual plants; pastoral nomadism is possible, but no rain-fed agriculture).
- **Semiarid**: \( 0.20 < P/PET < 0.50 \), the average rainfall is 150–500 mm a\(^{-1}\) and the interannual coefficient of variability is 30–40% (covered by open vegetation cover where perennial plants dominate; extensive livestock breeding is possible, also rain-fed agriculture which, however, remains hazardous).
- **Subhumid–dry**: \( 0.50 < P/PET < 0.75 \), the average annual precipitation is 500–800 mm, spread over a rainy season of 6 months. Aridity is a recurring seasonal constraint, and the interannual coefficient of variability may still reach 20% (permanent rain-fed agriculture is practised with cultures adapted to seasonal drought).

It is seen that all continents, including even Europe with its Mediterranean fringe, possess drylands where aridity and drought are the two most apparent climatic facts (aridity implies a permanent pluviometric deficit; droughts result from a temporary pluviometric deficit in relation to the normal precipitation). A more detailed review of arid ecosystem characteristics is provided by Goodall and Perry, special emphasis on arid soils is, for example, given by Dregne, and specific management issues are thoroughly discussed by Beaumont. In the following section, some of those issues which are of specific importance when the use of remote sensing for an
assessment of arid lands is taken into consideration are reviewed in more detail.

2.1 Climate and Vegetation

The average annual rainfall in arid to semiarid ecosystems roughly varies between 0 and 500 mm a\(^{-1}\) and, in general, remains below the potential evapotranspiration rate. The distribution of rainfall over time is highly irregular, such that dry spells may also occur during so-called “wet” periods. Since most dry ecosystems are characterized by frequently cloud-free atmospheres, global irradiance is higher than in most other ecosystems and, as ground albedo amounts to higher values than in more humid regions, radiation balance in arid to semiarid regions is only slightly positive, or even negative. Rock, soil and plant surfaces become intensely heated during the day whereas, owing to the low moisture content of the atmosphere and soils, temperatures decrease rapidly during night-time.

Plants of arid and semiarid ecosystems have to adapt to frequently occurring periods of heat and water stress by developing xeromorphic characteristics (e.g. reducing the size but increasing the number of leaves, increasing the number of stomata per leaf area, etc.). Typically, drylands possess an open vegetation cover; in moderately dry areas the vegetation is distributed uniformly where proportional cover appears directly related to the amount of rainfall or, more precisely, plant-available water. With severely increased aridity, i.e. under desert conditions, this uniform distribution is replaced by a concentration of plants in channels of the drainage network; this “contracted” vegetation rarely covers more than 10% of the surface.\(^7\) The sensitive nature of the vegetation cover in drylands is a result of their weak persistence and stability. This reflects both their dependence on precipitation (especially their variability) and their resilience, i.e. their capacity for rehabilitation when favorable conditions are re-established.\(^1\) It is a direct consequence that plant density or proportional cover is one of the most important parameters for assessing the resource potential or state of the environment in semiarid

Figure 1 World distribution of drylands.\(^2\) The different types are: 1, hyperarid; 2, arid; 3, semiarid; 4, subhumid–dry. [Reproduced by permission from Mainguet.\(^3\)]
regions, often more important than species composition. Differences in proportional cover may indicate climatic or hydrological gradients, or respond to effects of edaphic aridity (as described in the following section); vegetation changes over time may relate to climatic fluctuations and/or provide evidence for human pressure upon the environment. More important even, proportional plant cover as one of the most important environmental indicators is directly tangible through remote sensing systems,\(^8\) provided that specific precautions are taken with regard to the methodology of data analysis.

### 2.2 Soils

Apart from the soils of steppe areas (e.g. phaeozems, chernozems) with their particularly high amount of organic carbon, soil formation tends to decrease rapidly with increasing aridity since, owing to the almost continuous shortage of water, chemical weathering becomes less important than in humid regions. Soils in semiarid regions often have very little organic material and therefore consist almost exclusively of rock and mineral particles. Also, the importance of leaching processes (i.e. transport of soluble salts, carbonates, Fe and Al oxides, fulvic acids and clay minerals) is reduced and, under increasing aridity, is replaced by the movement of free carbonates and salts with ascending water (capillary rise). Arid soils (xerosols) are thus characterized by relatively high concentrations of carbonates, soluble salts and, depending on the parent substrate, SiO\(_2\)-rich components in the upper soil horizons. Frequently, these form hard crusts (i.e. calcrete, silcrete) close to the surface which considerably influence infiltration capacity and the soil water budget, but also the spectral properties of the surface. Microphytic communities tend to produce coatings on rock and soil surfaces in arid and semiarid areas.\(^9\) The mineral grains of soils are then held together by a fibrous mat of cyanobacteria and other biological elements;\(^10\) these biological crusts may considerably modify runoff and infiltration characteristics of the parent substrate\(^13\) and contribute to the stabilization of surfaces.\(^14\)

Although already mentioned implicitly, it must be emphasized that soil texture appears to be the most important factor for the water balance of arid soils as it controls infiltration and the capillary rise of water. In fine-textured (i.e. loamy) soils rainfall can hardly infiltrate and is therefore subject to evaporative losses. More coarsely textured soils (e.g. sandy or stony substrates) permit water to infiltrate rapidly to greater depths where it is well protected against evaporation after the topsoil layer dries out; additionally, almost all infiltrated water is readily available to plants, and salt concentrations in the soil remain low owing to the higher leaching efficiency. This implies that care must be taken as the postulated positive relation between increasing average rainfall and leaching intensity is to be modified with regard to local surface properties: water availability and therefore the rate of water infiltration and leaching are positively related to the rock/soil ratio (i.e. the proportion of runoff-generating rocky surfaces compared with the water-receiving soil surfaces per unit area). Relationships between climate and environmental conditions which are valid on a global scale therefore become problematic when local factors such as topography, lithology and soils determine the redistribution of water.\(^15\) It is therefore mandatory that remote sensing needs to focus on the precise characterization of surface properties if it is supposed to contribute to environmental assessments of arid lands, a point which needs to be discussed again in the context of the ongoing debate on desertification and climate change.

### 2.3 Land Use

Although drylands belong to the least densely populated regions of the world, extensive rain-fed agriculture and/or grazing are common features of the dry mid-latitudes or the subtropical regions. The frontier between these land use systems is drawn by a rainfall threshold up to which rain-fed agriculture is still possible; depending on temperature regimes, soil characteristics (i.e. edaphic aridity) and specific cultivation techniques (dry farming) this rainfall limit is reached between 250 and 350 mm a\(^{-1}\).\(^16\)

The main agricultural products of rain-fed agricultural systems in drylands are cereal crops (wheat, barley) which provide more than 50% of the world production. As the yield per unit area is relatively low, the farms tend to compensate for this by increasingly large production acreages and a high degree of mechanization. However, a sharp distinction needs to be made between developed and third-world countries: in the latter, the pressure of an enormous population growth severely limits the availability of land resources and imposes the need for more intense production systems (i.e. at the expense of higher risks of failing).

Extensive grazing in semiarid ecosystems is conducted in the form of either ranching or nomadism. Ranching is a modern organizational scheme for extensive grazing and was mainly developed in the USA and Australia, while grazing in the drylands of Africa and Central Asia is still dominated by nomads. One of the most important environmental risks results from exceeding the carrying capacity of the land by increasing the number of cattle per unit area. This does not only occur in well-developed economies but many cases are known where the abandonment of nomadism has led to severe land degradation processes which are usually summarized under the term “desertification”.\(^3,17\) Evidently, remote
sensing has to play an important role in monitoring the effects of such degradation processes where, once more, the focus has to be on the detection of surface properties related to vegetation and soil resources. On the other hand, remote sensing not only has to interact in the field of disaster assessment and mitigation but, even more important, in analyzing the resource availability for sustainable agricultural developments in drylands.

In many dryland ecosystems with accessible water resources, irrigated agriculture has been introduced. Of course, superb yields are guaranteed (often at the expense of excessive fertilizer and pesticide input into the system) as long as the water resources (frequently fossil groundwater) are not exhausted. Environmental problems usually result from high salt and Na concentrations in the soil, in particular when the supply of irrigation waters is not adequate to provide sufficient leaching. Remote sensing may primarily contribute to the resource management in irrigation areas by mapping the spatial extension of specific cultures (for which water consumption is known), or by detecting indications of salt accumulation in topsoil substrates. Efforts have also been devoted to the use of space techniques for deriving energy fluxes for water management.\textsuperscript{\textit{18–21}}

\section{3 REMOTE SENSING AND THE ASSESSMENT OF ENVIRONMENTAL CONDITIONS IN SEMIARID REGIONS}

Remote sensing is commonly introduced as the science of collecting information about objects without coming into physical contact with them; in earth observation the most important medium for transmitting this information is electromagnetic radiation in the optical and microwave region. There are numerous excellent textbooks available which give a thorough description of the physical background,\textsuperscript{\textit{22–24}} basic principles of image interpretation,\textsuperscript{\textit{25,26}} digital image processing,\textsuperscript{\textit{27–29}} and specific sensors and fields of application.\textsuperscript{\textit{30–35}} Most of these books, however, tend to emphasize either the optics and physics of remote sensing or digital image processing and sensor aspects.

Here, we shall attempt to treat remote sensing assessments of arid and semiarid ecosystems as a continuous process which includes aspects of energy – matter interaction, radiation propagation, sensor characteristics and image processing – an approach which has recently been devised as the image interpretation chain.\textsuperscript{\textit{36}} It is in the consequence of this approach that one has to go beyond emphasizing the general advantages of remote sensing such as providing a synoptic, repetitive and consistent perspective over large areas when discussing its suitability for environmental assessments. Primary importance should be attributed to analyzing more closely which relationships exist between parameters of interest and corresponding electromagnetic signals from the earth.

\subsection{3.1 The Importance of Assessing Surface Properties}

It is widely agreed that environmental change in arid, semiarid and dry subhumid ecosystems is not necessarily driven by climatological variables but frequently triggered by processes which result from adverse human impact on these fragile ecosystems.\textsuperscript{\textit{5,37}} Also, the productivity of dryland systems largely depends on surface properties which, as they control water availability and the spontaneous emergence and development of new plants and dust production during wind storms, might dominate climatic variables. It follows that surface properties are to be considered more indicative than long-term climatic conditions. The ability to draw concise conclusions with respect to land resources and environmental change will thus depend on the capability to assess specific surface characteristics (i.e. vegetation cover and composition, parent material and soils, including mineralogical and biological crusting) from remote sensing data, and to analyze multiannual time series of images. Here, retrospective studies might be as important as continuous monitoring of environmental change by remote sensing.\textsuperscript{\textit{38}}

In addition to the presence or absence of, and the temporal changes in, the abundance of photosynthetic and dry (i.e. woody) plant components, important surface properties for the assessment of semiarid ecosystems are the type of parent material (lithology), the proportion of rock and soil surfaces per unit area (as the rock/soil ratio carries important implications for water concentration and increased leaching capacities above climatic averages), specific soil properties (such as the content of organic carbon or iron oxides which assist in identifying whether a soil profile has been truncated by erosion processes, or whether it is to located in a sediment and nutrient sink), the presence of sand sheets and dunes (with their associated capability to protect infiltrated water against evaporation) and biological crusts (with their positive feedback on sand stabilization and runoff concentration). All these can play a decisive role not only in the assessment of land resources but also in the context of assessing desertification dynamics.\textsuperscript{\textit{17}} However, one has to abolish too simplistic views such as to expect that remote sensing assessments may automatically flag “desertified” regions by, for example, indicating a change in the proportion between potential and real evapotranspiration (notwithstanding the existing methodological problems). What remote sensing assessments can provide is to reveal physical changes in surface properties; however, whether the intrusion of a sand sheet, for example, is to be understood
as an indicator of desert encroachment (i.e. degradation) or as providing improved conditions for the infiltration of rainfall and its protection against evaporative losses (i.e. a resource upgrade), is to be decided by the user/expert in the local and regional context, respectively. Remote sensing, if handled with appropriate methodological and conceptual knowledge, provides quantitative and qualitative indicators but not directly their interpretation. Additionally, it must be recognized that the instantaneous state of the surface may fluctuate seasonally and/or annually in response to rainfall, illustrating the dynamic nature of the system. Repeated observations over longer time periods are therefore indispensable for assessing significant changes.

### 3.2 Remote Sensing Systems

When compared with the early 1970s when the first Landsat system was placed in a space orbit, remote sensing systems exhibit an enormous diversity in terms of spectral, spatial and temporal parameters, and which system is to be used depends on the user requirements (Figure 2). If a frequent repetitive coverage with relatively low spatial resolution is desired (e.g. for meteorology), one would certainly be inclined to base the approach on the AVHRR system available from the polar-orbiting satellites of the NOAA series, or even on data from geostationary satellites such as METEOSAT or GOES. Alternatively, one might look for the highest spatial and spectral resolution available, even at the expense of relatively low repetition rates, and would thus choose one of the available earth observation satellite systems (Landsat, SPOT, IRS).

The modern era of satellite remote sensing started with the multispectral scanner system (MSS) in 1972, which provided for the first time high-resolution earth images in digital form [four spectral bands in the visible (VIS) and near-infrared (NIR) region, 80 m spatial resolution, 180 × 180 km frame size]. Two identical follow-up systems (Landsat-2 and -3) were launched during the 1970s before, in 1982, the second Landsat generation with the Thematic Mapper (TM) [30 m spatial resolution (the thermal band of the Landsat TM has a spatial resolution of 120 m), seven spectral bands in the VIS, NIR and short-wave infrared (SWIR), and thermal infrared (IR)] and, in 1986, 1990 and 1993 the SPOT high-resolution visible instrument (HRV) with 20 m spatial resolution in three spectral bands, and 10 m resolution in a panchromatic

---

**Figure 2** Important operational, planned, and experimental remote sensing systems in a two-dimensional parameter space determined by spectral and spatial resolution. DAIS, Digital Airborne Imaging Spectrometer.
channel, became available. Recently, the importance of SWIR channels for operational satellite systems has been underpinned by the layout of the HRV and the vegetation monitoring system (VEGETATION) on SPOT-4. Also, the new concept of imaging spectrometry, i.e. the acquisition of reflectance signatures in numerous narrow and contiguously spaced spectral channels, has meanwhile provided the user community with a range of powerful, yet largely experimental airborne sensor systems such as the airborne visible and infrared imaging spectrometer (AVIRIS) and HyMap. Considerable efforts have been made to construct hyperspectral imaging systems which are able to observe the earth from space orbits; however, to find a suitable cost–benefit compromise the planned systems, such as the moderate resolution imaging spectrometer (MODIS) (to be provided by NASA) and the medium resolution imaging spectrometer (MERIS) on board the future environmental research satellite (ENVISAT) platform [European Space Agency (ESA)], will collect their high-spectral resolution data with rather moderate spatial detail (250–1200 m).

Which systems are to be considered the most useful ones for arid ecosystem observation is largely to be seen in relation to the basic considerations in the previous section. As most information on the composition of surface elements (vegetation, soils, rocks, biological crusts) is provided by passive remote sensing systems, we shall limit our discussion to sensors that measure electromagnetic radiation either emitted directly or reflected by the objects. Although spectacular images from Shuttle-based radar experiments have revealed the existence of palaeodrainage systems in the eastern Sahara, the use of active remote sensing systems (i.e. synthetic aperture radar) is, in arid ecosystem research, to a large extent still experimental, and the discussion on microwave remote sensing therefore is beyond the scope of this application article. Also, no emphasis is given to thermal sensors since a clear strategy to employ these systems in arid ecosystem research is not recognizable at the moment. With regard to the importance of surface properties in arid regions, there is of course a connection with geological applications of thermal remote sensing, but a direct link to nongeological resource assessments has not yet been established, apart from the use of thermal data for estimating fluxes in irrigated areas. The description of the energy exchanges at the earth’s surface represents a major sub-discipline of meteorology, where in particular the evapotranspiration term is of great interest to agriculture and water-use specialists. Although considerable progress in processing thermal IR images has been achieved, a major problem results from the fact that, in conjunction with the remote sensing data, explicit values of some meteorological variables are needed which are not readily found over large areas. Also, thermal remote sensing provides instantaneous measurements, and these can only be extrapolated to daily values under relatively stable atmospheric conditions; it is therefore not surprising that this type of approach has not yet achieved operational status.

The focus is therefore on air- and space-borne multispectral systems, including high spectral resolution sensors (i.e. imaging spectrometers), but also on color aerial photographs which still provide a cost-attractive yet efficient tool for surveying important ecosystem parameters in arid and semiarid environments. The traditional techniques of air-photo interpretation are well established and routinely used, and will not be considered in much detail. It is only to be mentioned that digital image processing has also opened up new avenues for analyzing aerial photographs. Emphasis will be primarily placed on the processing chain, i.e. on digital image processing, radiometric analysis and thematic concepts for assessing target properties.

4 REMOTE SENSING DATA ANALYSIS

Optical remote sensing systems measure the spectral properties of surfaces; they cannot measure specific resources or land degradation directly. The major problem associated with their use is to interpret quantitatively a measured signal that has interacted with remote objects in terms of the properties of these objects. This requires a thorough understanding of the radiation interactions with those elements that characterize the surface conditions in which we are finally interested.

However, before discussing appropriate scene models, one needs to understand the initial part of the processing chain (i.e. data preprocessing) which deals with the geometric rectification of digital imagery and with turning uncalibrated image gray values into physical quantities. Engineering data about the detector sensitivity (i.e. calibration coefficients) permit the multispectral scanner to reconvert an encoded digital number (DN) into measured radiance, and radiative transfer calculations can be used to correct for atmospheric effects, such that the surface-reflected radiance is restored from the satellite-measured signal. Dividing this term by the downwelling solar irradiance provides us with an important primary parameter which is termed bidirectional reflectance, (Figure 3); albedo and surface temperature are other primary parameters which, as a result of similar processing chains, can be derived from optical remote sensing systems.

The processing chain further involves appropriate scene models which can be used to convert primary parameters into thematic information. Here the problem
is not so much to identify a particular surface type, but to characterize it. A variety of methods have been proposed which range from empirical spectral indices to the design and inversion of physically based models. While the applicability of the various approaches depends on the nature and accuracy of the desired information and the availability of resources (i.e. sensor characteristics), an important prerequisite for their operational use is that they must satisfy specific requirements in terms of standardization and portability. Therefore, an important issue in satellite remote sensing is to conceptualize and streamline the data analysis in such a way that consistent indicators for environmental assessments can be obtained.

### 4.1 Data Preprocessing

In the context of this application article, not too much emphasis will be placed on the geometric rectification of digital images since the techniques and methods to be used are well described and considered largely operational.\(^{27,29}\)

More important are the methods which are used to compute primary (i.e. physical) parameters from gray-level images. Today, we are in the favorable situation that various radiative transfer codes are available which, if constrained with the same atmospheric parameters, provide consistent results.\(^{49}\) Frequently, atmospheric correction methods are employed which are based on the formulation of radiative transfer as developed by Tanré et al.\(^{50}\) Modifications have been applied to this concept in order, for example, to account for atmospheric extinction processes as a function of sensor and terrain altitude\(^{51,52}\) and to compensate efficiently terrain-induced illumination effects by incorporating digital elevation data into the correction process.\(^{53}\)

This modified 5S code (Figure 4) makes extensive use of analytical expressions and preselected atmospheric models, resulting in a short execution time. It provides corrections for atmospheric absorption, scattering and pixel adjacency effects, where diffusion and absorption processes are assumed to be independent. Upward and downward transmission coefficients are derived by introducing the auxiliary quantity of optical thickness \(\tau\) which measures the total extinction of a light beam due to molecular and aerosol scattering when passing through an airmass. Multiple scattering is accounted for, and the absorbing atmospheric gases (H\(_2\)O, O\(_3\), CO\(_2\), O\(_2\)) are assumed to condense at the top of the atmosphere and at the top of the layer between the earth’s surface and the sensor altitude. With this or comparable transfer codes, reflectance factor retrievals from the Landsat TM bands have been achieved with an accuracy of \(\pm 0.005\) to \(0.02\).\(^{55–57}\) and it is important to note that this level of precision can also be accomplished when the scattering optical depth is estimated from scene data itself.\(^{51}\) The major problem in retrieving reflectance factors from operational satellites lies in the sensitivity to the absolute radiance calibration of the sensors. However, there is an increasing awareness in the scientific user community towards this problem. In-flight calibrations for Landsat TM and SPOT data are conducted at various high-reflectance sites which is useful for determining at least an absolute radiometric calibration gain and monitoring the sensor degradation with time.\(^{58,59}\) However, it must be also noted that the successful use of radiative transfer calculations for high spectral resolution imagers depends on the availability of key parameters that adequately characterize atmospheric conditions during the flight (i.e. absorption optical depth, in particular that of water vapor).

Alternatively, corrections of radiometric scene-to-scene variations for retrospective and monitoring studies
can also be obtained through empirical approaches which are based on the analysis of radiometrically invariant surfaces.\(^{(36,60)}\) However, it needs to be recalled that these techniques only produce relative adjustments of variable scene radiometry as long as the reference scene is not atmospherically corrected. The use of scene models that are based on absolute reflectance might therefore be seriously restricted or impossible. Also, radiometric normalization is not able to account for nonlinear effects such as the variation of atmospheric conditions with terrain altitude, the reflectance contribution from the environment of a pixel and terrain-induced variations of illumination, and, therefore, reflectance.

### 4.2 Scene Models: Fundamental Considerations, Indicators and Interpretation Concepts

In order to assess land resources or land degradation processes, it is necessary to define diagnostic indicators. These may be primary indicators (e.g. high salt content in salinized soils) or secondary indicators which are produced by the problem (e.g. reduced vigor of vegetation). The most useful indicators are those which have distinct spectral signatures and are unique to a particular issue.\(^{\text{61}}\) As part of the scientific background to this application article, we therefore need to discuss some issues in more detail, such as principles of soil and vegetation reflectance, limitations of conventional vegetation indices, detection thresholds for photosynthetic vegetation, the influence of specific surface constituents in arid regions (i.e. biotic crusts, desert varnish) and spectral characteristics related to nonphotosynthetic vegetation and variable surface conditions. This is essential for evaluating the use of remote sensing for resource inventory and monitoring, and for selecting appropriate indicators and sensor systems. Besides, it should not be forgotten that the development of suitable indices derived from remote sensing measurements and their interpretation for resource assessments and the surveillance of degradation processes (desertification) also require a conceptual framework which allows one to draw concise conclusions with regard to land surface conditions. Although these underlying concepts might vary as a function of regional ecosystem characteristics (i.e. in relation to physiographic conditions such as parent material, aridity, etc.), it should be ensured that results from different regions can be consistently evaluated on a higher hierarchical level.

#### 4.2.1 Soil Reflectance Characteristics

The spectral reflectance of soils is a cumulative property which derives from the inherent spectral behavior of heterogeneous combinations of minerals, organic matter and soil water.\(^{\text{62}}\) The most comprehensive studies to derive a typology of soil reflectance classes were conducted by Condit\(^{\text{63}}\) and Baumgardner et al.;\(^{\text{64}}\) the latter measured the reflectance of 564 soil samples from soil series in the USA and Brazil in the wavelength range between 0.52 and 2.32\(\mu\)m, and they were able to define five major soil reflectance types which are identified by curve shape and the presence or absence of spectral absorption bands caused by organic matter content, iron oxides and soil minerals (Figure 5). It is believed that any observed soil spectrum resembles one of these spectral curves.

Reflectance spectra of moist soils exhibit strong absorption bands centered at 1.4 and 1.9\(\mu\)m (Figure 5) which, together with weaker absorption bands at 0.97, 1.20, and 1.77\(\mu\)m, are attributable to overtones and combinations of the fundamental vibration frequencies of water molecules in the soil. The bands at 1.4 and 1.9\(\mu\)m are broad, indicating an unordered arrangement of water molecules at various sites in the soil.\(^{\text{64}}\) The relevance of individual mineral spectra to soil reflectance was reviewed by Mulders.\(^{\text{65}}\) Although absorption features in the 2.0–2.5\(\mu\)m range are of limited use for the identification of soil characteristics (because soil materials are complex mixtures of primary and secondary minerals both of which can already be part of the parent material), spectral absorption in the VIS to NIR range conveys important information about the presence of iron oxides. Even trace amounts of hematite and goethite can cause absorption bands and, in spite of the difficulties outlined by Geerken,\(^{\text{66}}\) quantitative relationships can be established when only a limited range of soils, for example tropical soil types, are considered.\(^{\text{67}}\) Since soil color is largely determined by spectral absorption

---

**Figure 5** Characteristic soil bidirectional reflectance spectra. (A) Developed, fine textured soils with high (>2\%) organic matter content; (B) undeveloped soils with low (<2\%) organic matter and low (<1\%) iron oxide content; (C) developed soil with low (<2\%) organic matter and medium (1–4\%) iron oxide content; (D) moderately coarse textured soils with high (>2\%) organic matter content and low (<1\%) iron oxide content; (E) fine textured soils with high (>4\%) iron oxide content. [Reproduced by permission from Baumgardner et al.\(^{\text{64}}\)]
features, attempts have been made to relate spectral measurements to standard color description used for soil description, such as the Munsell Soil Color Charts. It was shown that soil spectra can be simulated from Munsell color data, and that soil color can be remotely sensed when a limited number of reflectance measurements from the VIS spectrum are available.\(^{(68,69)}\)

The essential question is how spectral characteristics, including soil color indices, can be used to assess pedogenic properties or the state of soil resources in arid, semiarid or subhumid ecosystems. It is difficult to provide a general answer on this issue. An approach which, without any doubt, is useful for remote sensing studies refers to concepts which consider soil development to be either progressive or regressive with time.\(^{(70)}\)

Under progressive development, soils become better differentiated by horizons, and horizon contrasts become stronger. Pedogenetic processes involve the formation of clay-sized particles by weathering of larger grains, the alteration of clay minerals to other clay-mineral species, and the release and accumulation of iron by weathering. Some solids (silt, clay and CaCO\(_3\)) and ions (Ca\(^{2+}\), Na\(^+\), etc.) dissolved in rainwater are added from the atmosphere, and topsoil organic matter contents increase with the decomposition of plant and animal residues. Transfers within the soil profiles result in the accumulation of silt and clay, Fe, Al, CaCO\(_3\), gypsum or halite in the B horizon, or, owing to bioturbation processes, to the soil surface. In contrast, regressive pedogenesis refers to the addition of material to the surface at a rate that suppresses soil formation (i.e. eolian dunes, sand encroachment, glacial moraines, distal fans, etc.), or suppression of pedogenesis by surface erosion. Both progressive and regressive pedogenesis cause alterations of the soil surface that, to a certain extent, are spectrally detectable.\(^{(53,71,72)}\)

Under more humid conditions (i.e. more than 300 mm annual rainfall) this may be related to the intensity of soil brunification and rubification; another indicator may be the organic matter content of the topsoil material.\(^{(73)}\) However, it must be kept in mind that, in well-developed soil profiles, such models may not be applicable because extensive erosion may also occur without exposing the subsoil or zones with significant changes in soil mineralogy. In more arid ecosystems additional effects such as the soil/rock ratio, sand encroachment into rocky or loessic environments or the presence of biotic crusts may become very important.\(^{(15)}\)

As this concept seems to provide a widely applicable, general framework for the successful use of remote sensing techniques, the objective of differentiating between more or less favorable areas merely condenses on classical detection problems, i.e. to identify specific tracers or substances or surface expressions, and then to define optimized methods for maximizing the detection capabilities based on specific sensor systems. The methods to apply cover a wide range, including semiempirical relations between specific spectral variables and soil parameters, spectral mixing models and color indices derived from two or more spectral variables in the VIS range of the optical spectrum. Some examples will be reviewed more closely in section 5. Although the potential for mapping soils on a compositional basis seems to increase through the advent of hyperspectral imaging systems, a number of problems remain: the effects of vegetative cover must be separated from the mineralogical response, and the influence of the moisture content on the signal (which is intrinsically variable) must be efficiently compensated. It should also not be forgotten that erosion mapping using the vegetation response has been successfully adopted as an alternative approach.\(^{(74)}\)

Vegetation in dryland systems, however, exhibits specific characteristics which are discussed in the following section.

### 4.2.2 Reflectance Characteristics of Vegetation in Dryland Systems

Although sparse vegetation communities, typical of deserts and semiarid regions, make only a small contribution to the global carbon pool, they are an important indicator for environmental conditions, including disturbances introduced by human actions. The high spectral contrast of vegetation relative to soils has provided many successful studies which use optical remote sensing systems for observing vegetation communities.\(^{(75,76)}\)

Since plants have a distinct spectral signature with low reflectance in the VIS part of the spectrum and high reflectance in the NIR region, attempts have been made to use this spectral feature for estimating green vegetation cover and biomass through various, but functionally equivalent, “vegetation indices”.\(^{(77)}\) The most widely used indices are the simple ratio (SR) and the normalized difference vegetation index (NDVI) defined as

\[
\text{SR} = \frac{\rho_{\text{NIR}}}{\rho_{\text{RED}}} \quad \text{and} \quad \text{NDVI} = \frac{(\rho_{\text{NIR}} - \rho_{\text{RED}})}{(\rho_{\text{NIR}} + \rho_{\text{RED}})},
\]

where \(\rho_{\text{RED}}\) and \(\rho_{\text{NIR}}\) is the measured reflectance in the red and in the NIR spectral regions, respectively. These indices have frequently been used with the AVHRR data from the NOAA satellites, but also with high spatial resolution instruments, such as SPOT or Landsat.

The plant cover of arid regions usually consists of perennial plants (which are neither abundant nor very dense) and some short-lived (i.e. annual) herbaceous vegetation (which only appears for some weeks after the rainy periods). However, owing to their morphological and structural adaptations, the spectral response of the perennial plants in dry ecosystems is different from the typical reflectance of green plants. Because water
and chlorophyll pigment contents of the green leaves are low and the dominant parts of perennial desert plants are woody components, one finds that important spectral features of photosynthetic plants (i.e., chlorophyll absorption around 450 and 670 nm, the steep spectral transition of the red edge between 650 and 750 nm, and liquid water absorption around 1450 and 1950 nm) are much less developed than in plants from more humid regions. [This, of course, is not the case for irrigated crops with sufficient water supply (Figure 6).] The spectral response of vegetation in arid areas thus depends mainly on the proportions of green to dry and woody parts. An additional complication is introduced through the fact that dry and woody plant material exhibits not a unique but a highly variable spectral response, depending mainly on the level of plant decomposition.\(^{78}\)

A commonly used approach for retrieving vegetation parameters from spectral vegetation indices involves principally three steps: \(^{(79)}\)

- for a given date of satellite overpass, the derivation of a relationship between a spectral vegetation index and one vegetation parameter, based on the statistical analysis of satellite-derived index values obtained from a sample of contrasted reference sites with known values of fractional cover of green vegetation \((F_g)\) or leaf area index (LAI) (from simultaneous ground measurements);
- inversion of the relationship and application to each pixel of the image encompassing the reference sites;
- spatial and temporal extrapolation of the results.

The last point is the more problematic, because empirical relationships may be valid only within the limited range of vegetation and soil conditions occurring within the studied area and therefore not transferable to other situations.\(^{80}\) Nevertheless, some empirical relationships between NDVI and fractional cover \((F)\) or fractional cover of green vegetation \((F_g)\) have been proposed\(^{80,81}\) but, as NDVI is influenced by soil albedo variations,\(^{82}\) it is suggested that one should use “soil-adjusted” or orthogonal indices, especially in the case of sparse canopies. Other limitations in deriving regression-type relationships between spectral vegetation indices and ground-measured structural parameters are due to measurement errors in the field. The number of direct measurements is generally low because they are time-consuming and labor-intensive, and indirect measurements may not provide consistently accurate estimates of vegetation parameters. Similar restrictions apply to estimates of the above-ground biomass,\(^{79}\) and it must be realized that the uncertainties of empirical relationships will easily increase owing to scale problems as a function of the sensor spatial resolution.\(^{83}\)

Some concern has also been expressed about the sensitivity of spectral vegetation indices to the state of the atmosphere, illumination and observation geometry, and, in particular, the background reflectance of soils and rocks.\(^{84,85}\) While some of these disadvantages can be compensated by the use of atmospheric corrections and/or by compositing a number of days of data, Pinty and Verstraete\(^{76}\) have proposed an alternative index [global environment monitoring index (GEMI)] which is assumed to compensate for most atmospheric and illumination conditions. However, this new index also is not able to overcome the major drawback of two-band indices, which is the contamination of vegetation abundance estimates due to the background reflectance of soil and rock surfaces. Recently, it has once more been shown by Price\(^{46}\) that bare soil spectra alone may occupy already the lower 30% of the usable NDVI value range between 0 and 1 (Figure 7). In view of these undesired properties, we would of course prefer to use an approach which subtracts, or corrects for, the contribution of soil-reflected radiation instead of accepting the resulting measurement uncertainty.

Several modifications have been suggested\(^{84,86–88}\) which reduce primarily the influence of moisture-induced soil brightness differences but not the influence of wavelength-dependent variations in soil–rock spectral response. However, they do not provide a generic solution for compensating the side effects from spatially variable substrate types. To summarize, a breakthrough based on the use of band ratioing techniques, i.e. within the concepts of two-band indices, could only then be expected when soil spectra would exhibit no slope between 0.6 and

---

\(F_g\) or fractional cover of green vegetation

**Figure 6** Spectral reflectance of photosynthetic plants (\(\text{Pinus halepensis}\)) compared with a spectrum of desert shrub (\(\text{Artemisia herba alba}\)) which includes a large proportion of dead stems and litter.
Rocks and soils are exposed to various processes that strongly affect their surface characteristics. A major effect of chemical weathering is an enrichment of Fe-bearing minerals at the rock surface. Good solubility of iron in connection with capillary force and precipitation supported by bacteria results in limonitic crusts that, owing to Fe charge-transfer bands induced by the iron-rich crust, cause strong absorptions in the VIS range between 0.4 and 0.6 µm. The dominant spectral effect in the NIR and SWIR region is a uniform decrease in overall reflectance, but the increase in absorption in the VIS range might simulate a substrate richer in iron than actually present.\(^{(66,89,90)}\) Also microphytes form coatings on rock and soil surfaces in arid and semiarid areas,\(^{(9)}\) where the kind of populating organisms (mosses, lichens, algae, fungi, bacteria and cyanobacteria) often depend on the orientation of rock surfaces. In the Negev highlands of Israel, for example, south-facing surfaces of limestones are populated by endolithic cyanobacteria carving pinhead holes, whereas north-facing surfaces are covered by epilithic lichens forming smooth-faced coatings.\(^{(91)}\) The effects of various lichens on the spectral behavior of rock surfaces can hardly be predicted, and in addition to overall intensity changes (albedo) we also find a dependence of spectral response on the type of microphytes.\(^{(89)}\)

On sandy substrates one frequently finds biogenic crusts, where the mineral grains are held together by a fibrous mat of cyanobacteria and other biological elements.\(^{(15)}\) The influence of the crust on runoff and infiltration capacity was, for example, examined by Yair,\(^{(13)}\) and their spectral properties have been studied to some extent by Karnieli and Tsoar\(^{(92)}\) and Hill et al.\(^{(48)}\) The photosynthetic activity of microphytes, algae and mosses causes spectral absorption due to chlorophyll around 670 nm, which is expected to influence abundance estimates of vascular plants derived from multispectral remote sensing data. Hill et al.\(^{(54)}\) had noticed similar effects when measuring green foliage cover with high spectral resolution data over lichen- and algae-covered limestone surfaces in France: sparse vegetation was overestimated when it occurred on limestone/lichen-covered background which provided a photosynthetic component on its own. However, they could also demonstrate that improved estimates were obtained when the corresponding background spectrum was introduced in the analysis.\(^{(53)}\)

### 4.3 Improved Scene Models: Detecting Surface Properties Based on Spectral Decomposition Modeling

With regard to the approaches discussed so far, one needs to draw attention to the fact that uncertainties in measuring vegetation abundance with optical sensors can be minimized by accounting for the reflective properties of sometimes highly variable background materials.\(^{(53,93)}\) Conversely, natural vegetation can significantly mask and alter the spectral response of the ground. Therefore, instead of attempting to develop separate soil- or vegetation-related indices which are based on spectral reflectance measurements in single or multiple bands, it seems more appropriate to use dedicated spectral decomposition techniques.

One of the most promising approaches for computing the proportional abundance of materials which occur within a specific surface area (i.e. pixel) is based on computationally decomposing multispectral measurements with reference to a finite number of pure spectral components, i.e. endmembers (Figure 8). The method has

![Histogram illustrating the number of soil spectra having given values of NDVI, at intervals of 0.01. The spectral data are from 564 spectra contained in the Purdue University soil spectral database (see also Figure 5). [Modified after Price.\(^{(46)}\)]](#)
become known as SMA,\(^{(94,95)}\) and it assumes that most of the spectral variation in multispectral images is due to mixtures of a limited number of surface materials, and that these mixtures can, to a first approximation, be described as a result of additive (linear) spectral mixing (i.e. where each photon contacts only type of surface material). Either multiple scattering would need to be accounted for with nonlinear models or the variables of the linear mixing equation would need to be delinearized by using, for example, single-scattering albedo instead of reflectance.\(^{(96)}\) The computation of proportional abundances can then always be solved with a system of linear equations. In matrix notation one can write Equation (1)

\[
A \cdot X = B
\]

where \(A\) is the \(m \cdot n\) matrix of spectral endmember signatures (usually derived from so-called spectral libraries, i.e. a suitable collection of laboratory and field measurements), with each column containing one of the endmember spectral vectors. \(X\) denotes the \(n \cdot 1\) unknown vector of abundances and \(B\) the \(m \cdot 1\) observed data vector (i.e. measured reflectance of one pixel). The unknown vector of abundances is calculated with Equation (2)

\[
X = A^{-1} \cdot B
\]

i.e. essentially by inverting the endmember matrix. Evidently, a unique solution is possible as long as the number of spectral endmembers corresponds to the number of spectral bands. Also, if the problem is underdetermined, i.e. the number of unknown fraction components (i.e. abundances) exceeds the number of useful spectral bands by one, a solution can still be obtained by assuming that the set of endmembers is exhaustive (i.e. the sum of the computed endmember fractions is equal to one). This assumption, however, is not unproblematic since it is difficult to be sure that a sufficient number of spectral endmembers have been defined for a given data set. However, the typical case encountered in spectral unmixing (in particular when hyperspectral data are used) is that the number of bands is greater than the number of endmember spectra. The linear mixing model then becomes overdetermined such that the endmember matrix cannot be inverted. In this case a solution can be obtained through the pseudoinverse Equation (3)\(^{(97)}\)

\[
X = (A^T A)^{-1} A^T \cdot B + \varepsilon
\]

which minimizes the mean-square error in fitting the abundance estimates to the data, and renders the computation of abundance estimates equivalent to a rotational transform of the image.\(^{(29)}\) The added term \(\varepsilon\) represents the residual error of the model.

As the specification of endmembers is one of the major problems in spectral unmixing, it is an important feature of the method that the validity of mixing models can be analyzed by calculating error terms, such as the average root mean square (RMS) or spectral band residuals (i.e. \(\varepsilon\)). The average RMS error for the image provides a measure for how much of the spectral variability was explained by the selected endmembers, and the image of the RMS error for each pixel indicates such objects which could not be adequately modeled. In particular, the latter provides valuable indications for identifying which spectral components are not represented in the model. The spectral band residuals provide additional indicators of modeling errors. They are calculated by subtracting the modeled reflectance in each spectral band from the original sensor-measured reflectance. Positive residuals occur when the measured spectrum has higher reflectance at a specific wavelength than the modeled spectrum, indicating that the modeled spectrum contains absorption features which were lacking in the measured reflectance signature. Negative band residuals indicate the presence of absorption features in the measured spectrum which are absent or less pronounced in the modeled spectrum. Both the overall RMS error and the band residuals provide important diagnostics for handling uncertainties of the mixture model and for its optimization.

5 REMOTE SENSING OF SEMIARID LANDS: FROM RESOURCE ASSESSMENTS TO REGULAR MONITORING OF LAND DEGRADATION PROCESSES

Depending on the scientific perspectives, a variety of approaches and strategies have been proposed for assessing environmental characteristics of arid, semiarid and
subhumid ecosystems based on remote sensing.\textsuperscript{(98)} The different perspectives expressed therein not only emphasize methodological preferences but, more fundamentally, reflect important paradigms of scientific disciplines. It has already been argued earlier why this application article concentrates on remote sensing approaches which are focused on the characterization of surface properties and not on climatological variables. The reason is not so much that general circulation models have not yet been able to suggest unequivocally whether global warming will result in a decrease or increase in rainfall in the subtropical belts. It is of even greater importance that they are not able to account for regional or local scale variations in surface properties (i.e., lithology, topography, soils and biological variables) which, in dry ecosystems, exert a strong influence on the environment and control water availability.\textsuperscript{(15)}

After the International Convention on Desertification of the United Nations (i.e., a framework for programs on national, subnational and regional levels) entered into force, the need to measure land degradation processes increased. Whereas standard methods for undertaking such measurements are imperfect or expensive,\textsuperscript{(99)} satellite-based remote sensing offers considerable potential. However, the relatively low spatial resolution provided by remote sensing satellites implies that it is impossible to detect small features such as rills or gullies, or to identify the mix of plant species or to detect species change over time. Instead, one needs to exploit the spectral contrast between soil and vegetation and their intermediate states to develop surrogate measurements of degradation. Operational techniques, however, have been implemented in only a few locations; some dedicated research projects are, for a considerable part, funded by the European Union (e.g., DeMon-I and DeMon-II; see also Lacaze et al.\textsuperscript{(79)} and Hill et al.\textsuperscript{(100)}, and are expected to provide guidelines for the implementation of more standardized approaches in the near future.

5.1 Vegetation Assessments and Monitoring in Dryland Systems

As already mentioned, one of the most important surface characteristics of arid regions to be assessed by remote sensing is vegetation cover. Appropriate management of arid lands requires information on cover classes and vegetation types on relatively bare lands, and the extent of changes due to management as opposed to changes from natural causes.\textsuperscript{(61)} Arid lands are particularly suited to remote monitoring,\textsuperscript{(101)} and Graetz,\textsuperscript{(102)} for example, considers the use of satellites as the only way in which arid rangelands in Australia could be adequately monitored.

Although the differentiation between photosynthetic and dry vegetation is largely dependent on the available spectral range (it is obvious that sensor systems involving spectral bands in the SWIR region provide better data to separate green and dry vegetation components; this is, among others, one reason for which the new HRV system on board SPOT-4 has been equipped with one spectral channel around 1.65 $\mu$m). Pickup et al.\textsuperscript{(103)} in Australia have already been able to produce reasonable estimates of vegetation cover involving green and dry biomass even with Landsat MSS data (which only provide spectral bands in the VIS and NIR part of the spectrum). A specific problem in using optical remote sensing systems for mapping and quantifying vegetation in arid lands is the question of what amount of green foliage is detectable with air- or space-borne instruments. Siegal and Goetz\textsuperscript{(93)} had already demonstrated that significant changes in the reflectance characteristics of bare substrates need a vegetation cover of more than 10%, and that above 30% vegetation cover the vegetation-related signal component becomes more important than the soil reflectance. This by no means implies that vegetation cover below 30% is not detectable by remote sensing systems. Here we must emphasize again that ratio-based vegetation indices provide the worst estimates. Only vegetation indices which attempt to measure the abundance of green foliage with respect to a red versus NIR baseline (e.g., the “perpendicular vegetation index” proposed by Richardson and Wiegand\textsuperscript{(86)}) tend to perform somewhat better, but appear still worse than conceptually different approaches developed under the spectral mixing paradigm.

SMA has been successfully used for a wide range of applications in geology, ecology, land use and land degradation studies and even coastal water mapping.\textsuperscript{(54,104)} Owing to its direct response to preselected component spectra (i.e., typical desert shrubs and appropriate substrates) and increased robustness against soil color differences in the absence of dense vegetation, the method appears suited to overcome the conceptual limitations of two-band vegetation indices, such that we can expect improved estimates of vegetation abundance in areas with a sparse cover of mainly woody plants. Graetz and Gentle\textsuperscript{(105)} and Pech et al.\textsuperscript{(106)} have already used mixture models to estimate cover in arid Australian landscapes, and the technique has been successfully applied to Landsat TM images for mapping vegetation cover in semiarid parts of California (Figure 9). Although the scatter in Figure 9 is substantial, its orientation along the 1 : 1 relation between field-measured vegetation cover (in percent) and the vegetation fraction indicates an improvement in comparison with empirical relations between proportional cover and various vegetation indices. Also, not all of the variability in the estimated vegetation fraction should be attributed to the remote sensing estimates.
Some of it reflects methodological difficulties in assessing precisely the proportional vegetation cover, a typical problem with field observations (for low shrub communities of the bajadas, a consistent overestimation of the projected area of green leaves and woody biomass in the field records has been reported). However, part of the scatter may still be due to soil color variations or other background materials (rocks, woody components or litter), or to the nonlinear scattering of light which was known to play an important role for dense plant canopies with high LAI (i.e. irrigated areas). More recently, Ray and Murray demonstrated that nonlinear mixing is also important in the observation of plants in arid environments.

Since it is not advisable to compensate for background-related errors in vegetation abundance estimates by simply adding endmember spectra to the mixing model, Hill et al. proposed a strategy which aims at minimizing the number of endmember spectra while optimizing the selection of endmembers which describe the mixture of materials present in the background for each individual pixel. Spectral band residuals and, to a lesser extent, the RMS error of the model seem to provide valid criteria for controlling this selection. Their approach is based on the assumption that the mixed reflectance signature of a pixel is conditioned by three primary components which represent so-called “foreground” and “background” materials, and shade.

While a green vegetation spectrum constantly represents the foreground material (which may provide partial or complete cover of the ground), the background component is allowed to vary between various soils, parent rock types, senescent vegetation or leaf litter. This approach improved the vegetation abundance estimates for low coverage but also helped to identify the presence of dry plant matter, which inevitably provokes erroneous abundance estimates when using vegetation indices, no matter whether classical or improved indices are applied. It is believed that such developments in spectral unmixing hold some potential further to improve and standardize vegetation estimates in dryland systems. Moreover, it was demonstrated that spectral unmixing can also provide valuable information on soil composition when the spectral combination of components is conceptualized in the sense of intimate mixtures (as opposed to spatial-spectral mixing as determined by the sensor spatial response).

Besides the ongoing development of high spectral resolution airborne scanner systems, it has almost been neglected that aerial photographs with their extremely high spatial resolution (i.e. in the range of centimeters, depending on scale) can not only be used in the traditional way based on classical photointerpretation and/or photogrammetry approaches. The availability of high-quality scanning devices provides the possibility of generating multispectral images from aerial photographs which can then be analyzed by using classical image processing techniques. If spectral reference measurements are available it is even possible to calibrate color photographs to reflectance. As there are not many references available in the literature, the approach will be briefly illustrated by using an example from our own ongoing research on the disturbance and regeneration of biotic crusts in a sandy arid ecosystem of the Negev Desert (Israel). In this framework, digitized aerial photographs are used successfully to differentiate the proportional cover by photosynthetic and woody vegetation components (Figure 10). The methodological approach is based on SMA, which, after stratifying the aerial photographs into vegetated and nonvegetated spatial domains, provides the possibility of using reflectance spectra of specific components measured in the field.

5.2 Examples for the Assessment of Soil Characteristics in Dry Ecosystems

Not all studies of dryland ecosystems have relied solely on vegetation cover as an indicator of land suitability or degradation. Escadafal et al. and Hill et al. for example, have been able to use parameters indicative of soil conditions and hence to apply concepts taken from pedology and geomorphology to obtain qualitative
indications of soil degradation or erosion processes. SMA allowed the estimation of relative amounts of rock fragments and soil particles on the surface. Since, within a specific context, soil erosion leads to an increase in rock cover in source areas and the accumulation of soil material as colluvium elsewhere, rock content can be used as an indicator of degradation. This corresponds to defining the erosional state of soils as a function of the mixing ratio between developed soil substrates and parent material components which, of course, need to be spectrally distinct from each other. While Fischer\textsuperscript{111} has been able to adopt these principles for mapping soils of different ages in an area of young glacial deposits, Hill et al.\textsuperscript{53} successfully used this approach to map areas affected from soil degradation and erosion under sub-humid conditions in Mediterranean France.

They used a five-endmember mixing model which was applied to spectral field and laboratory measurements of soils, and later to multi- and hyperspectral images. According to taxonomic criteria, soil depth, and surface constituents, these soil spectra had been assigned to four soil condition levels (I, fair; II, degraded; III, severely eroded; and IV, parent rock). It was assumed that the surface reflectance characteristics of well-developed soils predominantly respond to the spectrum of a corresponding prototype spectrum, whereas those of degraded (i.e. eroded) or undeveloped soils produce increasing fractions of parent rock material (in this case limestone and marls) owing to the increased content of stone fragments and chemically unaltered material. Applying this approach to process real earth observation satellite images, of course, requires that the images were corrected for atmospheric effects (see section 4.1). Normalizing the estimated mixing proportions with regard to the shade and vegetation abundance allows one to retain only that part of the signal which relates to the soil reflectance. A soil condition map can then be obtained through a combination of cluster analysis and automatic classification of the corresponding images where user-defined thresholds (Figure 11) have to be observed. In both cases, the overall mapping accuracy for the above-mentioned four soil condition levels exceeded the 75\% level.\textsuperscript{53}

Similarly, based on digitized and calibrated high spatial resolution true-color aerial photographs, Hill et al.\textsuperscript{48} could also demonstrate that spectral unmixing of reflectance signatures from the nonvegetated domain allowed the successful identification and spatial differentiation of substrates and biological crusts in a sandy arid ecosystems (Figure 12). Based on hydrological concepts, Pickup and Chewings\textsuperscript{112} in Australia developed the erosion cell approach whereby the landscape is divided into

---

**Figure 10** Cross-section through individual desert shrubs in a sandy arid ecosystem of the Negev Desert (Nizzana, Israel). The diagrams which are based on the spectral unmixing of true-color aerial photographs\textsuperscript{48} show the proportional cover of photosynthetic and woody vegetation against the sandy background.
the production zone, where there is a net soil loss, a transfer zone with intermittent erosion and deposition and a sink where accumulation occurs.

Both approaches can be combined with quantitative estimates of soil properties such as organic carbon, thereby leading to increasingly differentiated possibilities to analyze environmental conditions in dryland ecosystems. Relating proxy data from a semiarid ecosystem in SE Spain (average rainfall 300–350 mm a$^{-1}$) to the erosion cell approach, Hill and Schütz\cite{Hill:1973} for example, suggest that organic carbon in xeromorphic soils can be understood as a tracer substance which highlights areas of accumulation and relative stability (sediment sinks) where soil conditions are favorable because of higher infiltration and water retention capacity, better aggregation and increased nutrient availability.\cite{Hill:2011} Based on this premise, the objective of differentiating more favorable sink areas from active erosion and transport zones on the basis of optical remote sensing images merely condenses on a detection problem, which is to identify the organic matter content of dryland soils based on spectral indicators. Although the general relationship between organic matter and soil brightness and color have long been recognized, quantitative relationships are difficult to obtain because albedo is influenced by additional properties such as soil moisture, content of iron or mafic minerals. However, summarizing the results of a review paper by Schulze et al.\cite{Schulze:2011} one can state that such relationships can be developed within and even among soil landscapes if soil textures do not vary too much. Soil texture also controls whether relationships between soil organic matter (SOM) and soil color are linear (in silty and loamy soils) or curvilinear (sandy-textured soils). Consequently, the relationship between organic matter and soil color (here to be understood as a surrogate of spectral reflectance in the VIS region) may only then become unpredictable if the soil texture varies too widely.\cite{Schulze:2011}

While more advanced procedures such as multiple-scattering models applicable to soil reflectance are still in

---

**Figure 11** The separation between undisturbed soils and degraded/eroded substrates, displayed in a ternary diagram of endmember abundances resulting from the unmixing of reflectance spectra with a three endmember model (one soil and two parent material components). [Modified after Hill et al.\cite{Hill:2011}]

**Figure 12** The sequence of diagrams on the right relates to estimates of the relative proportion of sand (dark gray), silt/clay (black) and biological crust material (light gray) in the surface material along a sampling transect at the Nizzana Research Site (Negev, Israel).
their infancy as they do not yet fully incorporate fundamental soil properties such as moisture content, organic matter content and structure, empirical relations still play an important role. Some of the classical relations between organic carbon content and spectral variables were based on the reflectance in the VIS range. Traditionally one has tried to analyze the relationships to soil color and soil brightness in the VIS range of the solar spectrum. In continuation of this work, major efforts concentrated on correlating specific spectral bands with SOM. More recently, Ben-Dor and Banin used the full reflective spectrum to predict SOM and other mineralogical and chemical soil properties based on multivariate statistics. Although they extended the approach to the Landsat TM bands, no application to real imagery was demonstrated. As this missing link is common to many studies, Hill and Schütz proposed a method which can be applied to high-resolution spectra in addition to the spectral resolution of the Landsat TM, and which can be applied to real images, provided that the data have been corrected for atmospheric effects (i.e. are available as primary parameter of the reflectance $\rho$). It is based on the fact that soil brightness is influenced by more parameters than organic carbon. Also, the specific influence of SOM on spectral reflectance is not expressed in narrow absorption bands, as is the case, for example, for iron oxides or carbonates, but it determines the overall shape of the reflectance curve in the VIS, NIR and mid-IR range of the spectrum (Figure 5). For this reason, they used the coefficients of a quadratic function (which was fitted to the original soil spectrum) to parameterize the most important characteristics of the original spectrum influenced by SOM, i.e. slope and curvature. Organic matter content (in weight percent) could then be estimated through a multiple linear regression between SOM and the coefficients of the parabolic curve fit; also, it was demonstrated that this model could be used to map successfully the organic carbon content in their study site based on atmospherically corrected Landsat TM images (Figure 13).

![Figure 13 Landsat TM-based map of soil organic carbon in the semiarid Guadalentin area in SE Spain, based on the relation presented in Hill and Schütz. In the image, gray levels correspond to SOM contents between 0.2 and 1.6%; areas of seminatural vegetation are masked. [Reproduced by permission from Hill and Schütz.]]
5.3 Monitoring Arid Ecosystems: the Desertification Issue

Resource assessments and continuous monitoring of environmental parameters are complementary issues to be observed for a sustainable management of dryland ecosystems. Therefore, an essential requirement for the applicability of remote sensing approaches is that suitable concepts and processing chains can be transferred and applied to locations with a wider range of climatic and lithologic conditions without changing too many of the processing parameters. Another important issue in monitoring is standardization, mainly because any improvements in the analysis may easily be incorporated into existing monitoring schemes if this implies only the reprocessing of already available primary parameter products or image-derived information layers.

Assessing and monitoring desertification by conventional means, in particular, have traditionally been lacking standardization because of the range of criteria and indicators. The various data sources available through remote sensing offer the possibility of gaining environmental data over both large areas and relatively long time periods. In this context, much attention has been given to using the daily global observations provided by the AVHRR on board the NOAA weather satellites. While it was initially believed that the disadvantages of the low spatial resolution (the pixel dimension varies between 1 and approximately 5 km at off-nadir positions) would be compensated by the benefits of spatial extensiveness and high temporal resolution, it is now well understood that the compilation of calibrated time series involves highly demanding processing chains and very careful consideration of calibration issues. The result is that suitable time series are almost exclusively provided by huge research organizations [e.g. NASA, Joint Research Center (European Commission) (JRC), Food and Agriculture Organization (FAO)] and, if data are desired at 1 km resolution, do not cover very long periods of time. Additionally, it had meanwhile to be accepted that, owing to its limited spectral and spatial resolution, the information content of the AVHRR data is not very suited to the application of high-level quantitative analysis procedures, and the well-known NDVI product suffers from the shortcomings described in section 4.

NOAA data have nevertheless been used to compare seasonal and annual biomass fluctuations in the Sahel and to study the complex spatial and temporal patterns at the Sahara desert front. Helldén could show that previously developed concepts of an advancing desert front in the Sudan were incorrect, and that changes in biomass were related to the variability of rainfall, giving evidence of a fast recovery of vegetation in wet years. With regard to the available earth observation satellite data archives (regular Landsat MSS data acquisition started in 1972 and Landsat TM coverage in 1983), we wish particularly to emphasize the importance of retrospective studies based on earth observation satellite images from Landsat MSS, TM and SPOT, which may provide better spatial scales and spectral information for understanding the present situation, but also for devising approaches for regular monitoring on local to regional scales. Long-term studies for degraded sites in semiarid to subhumid Mediterranean regions covering a time span of more than 25 years with earth observation satellites were conducted, for example, by Hill et al. Also their results revealed a largely differentiated evolution of mountainous ecosystems which in total had been considered as severely damaged by overgrazing. It seems obvious that the identification of degraded areas in the sense of an environmental inventory provides the fundamental basis for understanding better the processes of land degradation from their spatial context.

6 CONCLUDING REMARKS

Important characteristics of dryland ecosystems have been outlined to illustrate options for assessing and monitoring land resources and environmental change with remote sensing systems. Although it is unrealistic that remote sensing will replace traditional sources of data for inventory and monitoring, there is, without any doubt, an obvious role for it to play in assessing and monitoring the state of the environment in arid ecosystems. Unlike meteorological approaches which concentrate on the exchange of matter, momentum and radiation between the earth’s surface and the atmosphere, the importance of defining indicators and thematic interpretation pathways for the characterization of actual land surface conditions was emphasized. We have shown that both inventory and mapping of dryland systems are required to define the current status of resources and provide a baseline for monitoring, and that surveys must be repeatable and comparable, and therefore demand a standardized methodological framework.

The advantages of remote sensing result from its synoptic nature, comprehensive spatial information and objective, repetitive coverage. While remote sensing has initially been used primarily for resource mapping and inventory, it turns out that monitoring and predictive modeling are becoming more important and successful. However, no matter whether one intends to map surface properties or the objective is to estimate fluxes based on remote sensing, data require that the primary parameters, such as the spectral surface reflectance or surface temperature, are first retrieved with adequate
precision. This raises immediately the issue of adequate radiometric corrections. While atmospheric effects have been a significant factor in the failure of scene models (in particular for monitoring concepts), much progress has been achieved in the past years, and we are now in the position that large parts of the radiometric preprocessing are considered a routine operation, similar to geometric rectification. At present, the remaining problems in retrieving surface reflectance from satellite data appear related more to the absolute radiance calibration of the sensor systems than to methodological drawbacks. This ensures that more advanced scene models, such as the spectral mixing paradigm or invertible physically based analytical models, can be used to derive quantitative estimates and improved indicators for land resources and degradation processes.

Although several examples have been presented which appear suited for a standardized data analysis within operational schemes, additional efforts are required, in particular for the definition of suitable sampling schemes (i.e. the selection of monitoring sites which are representative of large eco-regions), for extending the thematic concepts for the interpretation of remotely sensed primary parameters as a function of ecosystem characteristics, for the incorporation of ancillary information (climatic records, lithology, topographic information), and for improving specific processing modules with respect to the physiographic variability of arid ecosystems. Finally, we wish to emphasize the importance of a retrospective analysis of earth observation satellite images which have been available since the 1970s. The integrated interpretation of the satellite-derived information layers, available climatic records and results from detailed field studies may in fact provide a new perspective to understanding environmental change in arid ecosystems.

The growth of Geographic Information Systems (GIS) has already greatly enhanced the integration of remote sensing with other types of data, opening up more and more pathways for the application of spatialized simulation models (concerning biomass production, runoff generation, soil erosion, etc.) which relate dynamic landscape processes to changes in spectral–spatial characteristics captured by remote sensing. Additionally, the satellite-based Global Positioning System provides high-precision geometric reference data for areas which were traditionally badly documented by maps. This is an additional element in the success story of GIS which are increasingly used to complement and improve the use of remote sensing data. The integration of remote sensing and GIS is expected to contribute substantially to assessing land capability for sustained production, to facilitate the identification of environmental indicators and interactions and to improve predictive capabilities. It thus forms the basis for drafting and implementing efficient land management plans which are needed to avoid land degradation under inadequate management practices.

Also, we are facing intriguing perspectives with regard to suitable sensor systems available in the future. Landsat 7, successfully launched in 1999, carries the Enhanced Thematic Mapper (ETM) with seven spectral bands in the VIS and IR portion of the electromagnetic spectrum, thermal IR capabilities and a panchromatic band with 15 m spatial resolution. The SPOT earth observation satellites, together with the series of Indian remote sensing satellites, provide a strong backup for operational applications, and there are indications that very high spatial resolution satellite systems, such as QuickBird and Ikonos (commercial 1-m panchromatic resolution satellites with 4–5 m resolved multispectral data from the VIS to NIR range) will become available in the future. Fusing data from high spectral and spatial resolution systems may significantly increase our observational capabilities. Besides the ongoing development of multi- and hyperspectral airborne scanner systems which, with the commercially available HyMap™ system developed by Integrated Spectronics Pty Ltd (Sydney, Australia), is approaching a phase of true operationality, it has almost been neglected that aerial photographs with their extremely high spatial resolution (i.e. in the range of centimeters, depending on scale) can not only be used in the traditional way based on classical photointerpretation and/or photogrammetry approaches. The availability of high-quality scanning devices provides the possibility of generating multispectral images from aerial photographs which can then be analyzed by using classical image processing techniques. If spectral reference measurements are available it is even possible to calibrate color photographs to reflectance and apply high-level image processing techniques, thereby providing a low-cost alternative.

Moreover, polar platforms will be launched by the USA and the ESA where advanced sensor systems for environmental monitoring will be placed, including hyperspectral imaging systems. It is also believed that new forms of synergism between low spatial resolution satellites with more frequent coverage (e.g. the NOAA AVHRR, the VEGETATION instrument on board SPOT-4, MERIS, etc.) and high spatial and spectral resolution systems should be devised; active microwave systems [e.g. European remote sensing satellite (ERS) 1 and 2 (of ESA), RADARSAT] are also expected to become more and more incorporated.

Further Reading

Spectroscopy started with the examination of the Sun’s light, making stellar spectroscopy the oldest branch of the subject. We describe modern stellar spectroscopy, and highlight some of the major successes in understanding the light output from stars and what we can deduce about the underlying objects. We present a description of stellar atmospheres considering the mechanical structure and the transport of energy. This leads on to a discussion of how the continuum and spectral lines of stellar spectra are formed and an explanation of the main features observed. The spectral lines observed in stellar spectra are then discussed and the information which can be obtained from examining their line shapes is examined. These include atmospheric pressure and temperature and both coherent and turbulent velocity fields (from stellar rotation and atmospheric convection currents). Magnetic fields, if large enough, may also be detected from careful examination of spectral lines.

Following a discussion of some practical aspects of observing stars, the main observational stellar classification scheme is presented, along with its interpretation regarding the underlying mass, radius, temperatures and evolutionary phase of the star. The effect of the chemical composition on line strengths is discussed, along with observational techniques of measuring it. The information which is obtained from different wavelength regimes – from radio waves to γ-rays – is presented, along with possible difficulties associated with observing in each regime.

Finally, we discuss what we have learnt from examination of stellar spectra and the current state of theory which is applied to them.

1 INTRODUCTION

The oldest branch of spectroscopy involves examining the light from stars – the field of spectroscopy started with experiments by Newton on the nature of light, using the Sun as his source. Helium was discovered by Lockyer in 1868 when examining emission lines in the solar spectrum (these lines actually originate from the solar corona). Since then, myriad applications of the technique have arisen, producing some significant advances in the study of matter. Spectroscopy has been a vital tool in the study of stars and has provided us with an excellent observational test bed on which to confront our theories. Here, we provide a brief introduction to some aspects of modern stellar spectroscopy.
Astronomy is a difficult science mainly because essentially all the information we receive from stars and galaxies is light. We cannot perform any experiments on the stars, we can only observe them – making this possibly the most extreme branch of remote spectroscopy as well as the oldest. This means that in order to understand anything about the universe, we must acquire as much information as we can from the photons we receive.

What, then, are our aims for stellar spectroscopy? The goals are to determine the physical conditions (pressure, temperature, density, chemical composition and ionization state) of the gas in a star’s atmosphere – from this we can describe the conditions of the emitting object as we see it. Then we can attempt to combine many such observations to constrain where that star is in its evolution by comparing them with theories of stellar formation and evolution. We also find information on rotation of the star and any other velocity fields in the atmosphere (turbulence and convection), and we can measure strong magnetic fields. Examining the same star at different wavelengths also gives us information about any circumstellar material, stellar winds and any natal gas left over from the star formation process.

There are several reasons why we should desire to understand stars: first of all for the stars themselves – they are large, powerful, nuclear-driven machines, with a wide range of temperatures and pressures in the same body. Therefore, it is obvious that our curiosity is aroused regarding the detailed formation and evolution processes. There are many questions in stellar astronomy still left to be answered, e.g. how exactly do stars form?, what does rotation do to a star?, what exactly happens in the center of a star?, how does the energy produced there propagate through the star?, what processes occur in the death throes of a star? These questions need a variety of physics to understand them – from fluid dynamics through atomic, nuclear and particle physics to optics. From this, we can use stellar evolution to study other physics; for example, we can provide tests of theories of general relativity, galaxy formation and evolution, cosmology and particle physics. Therefore, this is a considerable challenge!

Let us concentrate on stars, then. The light we observe originates from the very outer regions of the star; we can only see the atmosphere. Much of the information we can derive about the star is indirect and comes from comparing models of stars to our observations. From this technique, we can infer masses, radii, temperatures, internal structures, energy generation and transport methods of the stars, even though only perhaps several hundred stars have accurate masses and radii measured. The typical mass range of stars is from 0.1 solar masses \((M_\odot = 2 \times 10^{30} \text{kg})\) up to perhaps 100 solar masses. Radii range from 0.01 solar radii \((R_\odot = 6.96 \times 10^8 \text{m})\) up to a few thousand solar radii. Atmospheric temperatures of stars lie in the range from 1000 up to 50 000 K (the Sun’s atmospheric temperature is 5780 K). The temperature which characterizes the emission is termed the ‘effective’ temperature, \(T_{\text{eff}}\) – this is defined to be the temperature of a star with the same radius emitting a blackbody spectrum if it produced the same total emission. The total flux from the stars is \(F = \sigma T_{\text{eff}}^4\), where \(\sigma\) is Stefan’s constant. The total energy emitted by the star is this flux, multiplied by the total surface area of the star \(4\pi R^2\), or \(L = 4\pi R^2 \sigma T_{\text{eff}}^4\).

A star’s ingredients are hydrogen, making up around 70–75% by mass of the star, helium (around 25–30% by mass) and the rest (0.1–2%) the other elements in the periodic table – termed ‘metals’ in astronomy. A star is essentially a self-gravitating ball of gas which is prevented from collapsing under its own gravitational attraction by nuclear reactions in the central regions. The reactions mainly fuse hydrogen to helium, but in later stages of a star’s life fusion produces other elements up to iron. The energy liberated in these reactions diffuses outward from the star and eventually escapes into space, producing the photons we observe.

If we observe a sample of stars (e.g. several hundred of the Sun’s close neighbors), then we find that if we plot

![Figure 1](image_url)

**Figure 1** Plot of the effective temperature versus total output (luminosity) for the 300 nearest and 200 brightest stars (note temperature increases from right to left). The luminosity of the stars has been scaled to that of the Sun, which is represented by a filled circle (temperature \(\sim 5800\) K). The stars fall into three main groupings: a large band of stars from the bottom right-hand side to the top left-hand side (the main sequence stars), an area in the top right-hand side (the giant stars) and some stars in the bottom left-hand side (the white dwarfs).
the stars’ total output (luminosity) versus the effective temperature there are several distinct groups of stars (see Figure 1). The biggest group of stars (around 90% by number) are those which have temperatures from a few \(10^3\) to a few \(10^4\) K and radii from \(0.1R_\odot\) to tens of \(R_\odot\). These stars are termed “main sequence stars” and lie on a diagonal locus from top left to bottom right in Figure 1. Another group has high output and low temperature corresponding to the stars having large radii – the “giant” stars. White dwarfs are the low-luminosity, hot stars in the lower left-hand portion of Figure 1. As the main-sequence stars are the most numerous, we shall concentrate mainly on these.

The lifetimes of stars vary widely – the most massive stars (those which live the shortest time) have lifetimes of less than \(10^6\) years, whereas the low-mass stars (0.1 – 1 solar mass) live for \(>10^{10}\) years. The life of a star may be broken into three stages: the first is where the star forms and there are no significant nuclear reactions in the center (termed the “pre-main sequence” phase). Once on the main sequence, the stars spend most of their life (~90%) fusing hydrogen into helium. When the hydrogen fuel has become exhausted in the center then the star evolves off the main sequence and becomes a giant star. These “post-main sequence” stars lie on the upper right-hand side of Figure 1, and some of them eventually produce the hot white dwarf stars as remnants of their evolution.

What do we see, then? In Figure 2, the visible spectra of six stars spanning the main sequence are presented (see also Table 1). There are many changes from the hottest (the most massive) at the top of the figure to the coolest (the least massive) at the bottom. In this article we shall describe the emission from the stars and present the framework by which we can understand them.

### 2 STELLAR ATMOSPHERES – WHAT DO WE EXPECT TO SEE?

The physical conditions within a star vary enormously from the center to the surface. In the central regions (the core – comprising around 10% of the mass of the star), thermonuclear reactions provide energy to support the star against gravitational collapse, fusing hydrogen into helium. Temperatures in the cores of stars range from a few \(10^6\) to a few \(10^7\) K, depending upon the mass of the star. The energy created there travels outward through the star and is finally released in the atmosphere. As the body of the star is opaque to photons, then we cannot directly see the core and the only information we receive is from the outer layers (the atmosphere) of the star (in the case of neutrino astronomy, we can directly probe the core of the star, as the neutrinos do not interact with the rest of the star).

Although the atmosphere is rather small in its physical extent (for the Sun, the atmosphere is only \(~300\) km thick, compared with the solar radius of \(~7 \times 10^5\) km), it is very important that we understand both the structure and the way energy is transported in the atmosphere – after all, we obtain essentially all our information about the state of the star from this region.

A zero-order approximation to the radiative emission of any star is that it is a blackbody at a characteristic temperature \(T_{\text{eff}}\). Although this approximation is in fact
surprisingly good for most stars, in order to interpret the spectrum of a star correctly we must understand the region from which the photons we see come – the atmosphere.

2.1 Hydrostatic Equilibrium

Gas in the atmosphere is attracted towards the star due to gravity; it is prevented from collapsing by the pressure in the gas. The equilibrium attained when these two oppositely directed forces balance is called hydrostatic equilibrium. This leads to a relation between the radial pressure gradient of the gas $\frac{dP_r}{dr}$ at radius $r$, the mass within this radius $M_r$, and the density $\rho_r$ (Equation 1):

$$\frac{dP_r}{dr} = -\frac{GM_r \rho_r}{r^2}$$

where $G = 6.676 \times 10^{-11} \text{ N m}^2 \text{kg}^{-2}$ is the gravitational constant.

2.2 Physical State of the Gas

The gas in the atmosphere can be well approximated by an ideal gas and so the pressure is given by Equation (2):

$$P_r = \frac{k \rho_r T_r}{\mu m_H}$$

where $k$ is Boltzmann’s constant, $T_r$ is the temperature of the gas at radius $r$ and $m_H$ is the mass of a hydrogen atom. The new quantity here, $\mu$, is the mean molecular weight. This is defined as the average mass per particle, measured in hydrogen atom masses, e.g. for ionized hydrogen $\mu = \frac{1}{2}$ whereas for neutral hydrogen $\mu = 1$. In very hot stars, the pressure due to radiation has a significant effect and it must be taken into account. This radiation pressure is only a function of temperature, $P_{\text{rad}} = \frac{4}{3}aT^4$, where $a$ is the radiation constant.

From the outer edge of the atmosphere traveling inwards, the pressure increases, as do the density and temperature. The state of the elements in the atmosphere must also be taken into account when calculating its structure and emission properties – consideration must be taken into account of the ionization structure. This is determined via the Saha equation describing a collisionally dominated gas at temperature $T$ (Equation 3):

$$\frac{n_1}{n_0}P_e = \left(\frac{2\pi m_e}{h}\right)^{3/2} \left(\frac{kT}{2u_1(T)}\right)^{3/2} \exp \frac{-\eta}{kT}$$

where $n_1/n_0$ is the ratio of ions to neutrals, $P_e$ is the pressure exerted by the electrons which have mass $m_e$, $h$ is Planck’s constant, $\eta$ is the ionization potential and $u_1(T)$ and $u_0(T)$ are the partition functions of the ionized and neutral species, respectively, at temperature $T$. Finally, the excitation of each elemental species also needs to be calculated in order to discuss the flow of energy through the star (see below). The fraction of atoms (or ions) which are in the $i$th energy level is proportional to the Boltzmann factor and the statistical weight $g_i$ (Equation 4):

$$N_i \propto g_i \exp \left(\frac{-\chi_i}{kT}\right)$$

where the statistical weight is $g_i = 2J + 1$, where $J$ is the inner quantum number (e.g. for hydrogen $g_i = 2^J$), and $\chi_i$ is the excitation potential (the difference in energy between the bound state $i$ and the ground state).

2.3 Energy Transport in the Atmosphere

The energy created in the stellar core by nuclear fusion travels out toward the edge of the star and in the atmosphere it is finally able to escape, and so the star emits photons. The transport of the energy may occur by two different mechanisms: radiative and convective transport (in white dwarfs where the star is supported against gravity by electron degeneracy pressure, heat conduction by electrons may become important, but for the current argument, conduction is neglected as it is very small for most stars). Radiative transport is always present, but convective energy transport may only be present in certain regions of the star at certain times in the star’s evolution.

All stars have regions where the energy is transported radiatively (i.e. by photons) and convectively (i.e. by bulk motions of gas). Indeed, the energy transport mechanism has some effect on the evolution of a star, e.g. convection homogenizes the chemical composition of the star by mixing, whereas radiative transport does not. In physical terms, if a small parcel of gas is moved adiabatically in pressure equilibrium with its surroundings and it is less dense in its new position than its surroundings, then it will continue to rise – this region will therefore be unstable to convective motions. Convectively unstable regions obey the Schwarzschild instability criterion, relating the pressure and temperature gradients to those for an adiabatically stratified gas (Equation 5):

$$\frac{d \log T}{d \log P} = \frac{\gamma - 1}{\gamma} + \frac{d \log \mu}{d \log P}$$

where $\gamma$ is the ratio of specific heats. In convective regions the combined temperature and pressure gradients are large enough that it is energetically favorable to move the gas physically (i.e. convect) than energy transport via radiation. Note that the composition and ionization state of the gas enters into the instability criterion (via $\mu$) as this affects the equation of state (Equation 2). In the examples of atmospheres in Figure 3(a–d), convective regions are denoted by thick lines.
2.4 Outer Atmospheres – Chromospheres and Coronae

We have described the main ingredients from which the mechanical structure of a stellar atmosphere can be determined. Although these ingredients apply to all stars, there are extra physical effects which modify the outer regions of some stars’ atmospheres. In low–intermediate mass stars (masses up to about the solar mass), magnetic fields have a significant effect. When magnetic field lines twist owing to turbulence in the atmosphere, they may realign themselves to gain a lower energy state by breaking and reconnecting. The extra energy liberated in the reconnection process heats the gas at the outer regions of the atmosphere. For a solar-type star, the decrease in temperature with increasing radius is reversed owing to the magnetic reconnection heating and several hot layers are created – the chromosphere (having temperatures up to 25 000 K) and the coronae (temperatures up to $2 \times 10^6$ K). In fact, the thermal energy in the corona of the Sun is so great that the gas there becomes unbound and forms the solar wind.

2.5 Examples of Atmospheres

In order to calculate the full mechanical structure of the atmosphere, we must solve the equation for hydrostatic equilibrium (Equation 1) along with the equation of state (Equation 2) whilst at the same time solving for the ionization and excitation structure (Equations 3 and 4). Clearly this is a difficult process and is analytically intractable. Therefore, the equations are solved numerically. In Figure 3(a–d) the calculated atmospheres of some main sequence stars are shown. As can be clearly seen, the temperature, pressure and
electron density increase as we go deeper into the atmosphere and star. There is a significant change in all three models at \( \sim 0.9985 \) of the stars’ radii, which corresponds to the point where energy can escape from the star in the form of photons. To understand this characteristic point further, we must examine the flow of radiation through a star.

### 2.6 Radiation

The star loses its energy to the rest of the universe by photons escaping from the atmosphere. When considering radiative energy transport, the primary quantity to consider is the intensity of the photons \( I_n \) at a frequency \( n \): this is the amount of energy with frequency \( n \) travelling in a given direction per unit area, per unit solid angle. As they pass through the atmosphere, photons may be absorbed by atoms or ions, scattered in some direction, or created by an excited atom/ion or an ion recombining with an electron. The number of photons absorbed and scattered clearly depends on the number of photons present, so for a gas with absorption and scattering alone, the decrease in the intensity with distance is proportional to the intensity itself. Any extra photon emission from the gas depends only on the composition and physical conditions of the gas (this ignores stimulated emission, which is an excellent approximation). Therefore, we can write an expression for the intensity \( I_n \): the change in intensity \( dI_n \) in a distance \( ds \) is given by Equation (6):

\[
\frac{dI_n}{ds} = -\kappa_n I_n + \varepsilon_n
\]

where \( \kappa_n \) is the opacity of the gas describing the scattering and absorption processes and \( \varepsilon_n \) is the number of photons emitted each second per unit volume (both of which are functions of frequency \( n \)).

By dividing by the opacity, this equation (the equation of radiative transfer) becomes Equation (7):

\[
\frac{dI_n}{d\tau_n} = I_n - S_n
\]

where we have defined two new quantities. \( S_n \) is the source function. If the star is in complete thermodynamic equilibrium, or if the thermodynamic properties do not vary enormously over the mean free path of a photon (termed local thermodynamic equilibrium), then \( S_n \) is equal to the Planck blackbody function. Local thermodynamic equilibrium is usually a reasonably good approximation in stellar atmospheres, although many modern calculations do not use it – these solve for the excitation and ionization state exactly using a detailed calculation of the collisional and radiative processes. The other new quantity turns out to be extremely useful: \( d\tau_n = -\kappa_n ds \) is the optical depth and characterizes how far a photon will travel before it interacts: at an optical depth of unity, 63% of photons have been absorbed or scattered. Optical depths for stellar atmospheres are always measured from infinity inwards (Equation 8):

\[
\tau_n = - \int_{\infty}^{r} \kappa_n dr
\]

We find that at an optical depth of \( \tau_n = \frac{2}{3} \), the flux from the star is equal to the source function. Also, most of the radiation we receive originates at optical depths of less than \( \frac{2}{3} \), and so this value is conventionally used to describe how far we can ‘see’ into a star’s atmosphere. The surface at \( \tau_n = \frac{2}{3} \) is called the photosphere. Note that the physical location of the photosphere is dependent upon frequency \( n \) through the opacity. Hence at different frequencies, we see to different physical depths in the atmosphere.

### 2.7 Gray Atmospheres

There are three sources of opacity present in atmospheres: bound–free absorption, free–free absorption and bound–bound absorption. The first two of these have free electrons as their final state, whereas the last involves an electron jumping between two bound states in an atom or ion. Bound–bound transitions therefore give rise to spectral lines, and involve very specific energies (and hence wavelengths) of photons, whereas the first two can involve many wavelengths, and so provide a continuous absorption coefficient.

Although the opacity is a function of frequency \( n \), it is often averaged over all wavelengths when calculating model atmospheres – called the gray opacity. Examples of the gray optical depth (i.e. that from the gray opacity) are shown in Figure 3(b) for the model atmosphere examples. It is worthy of note that where the optical depth becomes less than a few, there is a severe change in the thermodynamic quantities – clearly radiation (and hence energy) may escape out of these regions. Also note that the atmosphere may be optically thin \( \tau < \frac{2}{3} \) in regions which are convecting for some stars. This allows us to “see” the convective motions in the atmosphere.

### 2.8 Formation of Continuum Emission

In the visible–radio wavelength regime, the continuous absorption coefficient tends to be dominated by hydrogen for all but the hottest stars (where helium free–free and bound–free opacity is important) and the coolest stars where molecules form in the atmosphere. At shorter wavelengths [into the ultraviolet (UV)], Rayleigh scattering off metallic ions can become important.

As hydrogen contributes most to opacity, let us use it as an example – many other elements show similar features in their continuous absorption coefficient. For
temperatures higher than $\sim 8000 \text{K}$, the bound–free opacity dominates, whereas below this level, it is the $\text{H}^-$ ion which provides most of the opacity (below $16000 \text{Å}$ via bound–free transitions, above via free–free transitions). Bound–free absorption introduces “edges” into the opacity corresponding to wavelengths where the atom is ionized from a particular level. For example, there are absorption edges at 912, 3647 and 8206 Å as the atoms with electrons in principle quantum number $n = 1$ (Lyman), $n = 2$ (Balmer) and $n = 3$ (Paschen), respectively, are ionized. Of course, the free–free opacity does not show any edges.

The total opacity is the sum of all the individual opacity weighted by the number distribution of hydrogen atoms in each excited or ionized state governed by the Boltzmann equation. We present three examples of the total continuous absorption coefficient due to hydrogen in Figure 4, where we have broken the opacity down into its constituent parts.

What effect does the variation of the opacity with wavelength have on observations? Assuming local thermodynamic equilibrium, the source function $S_\nu$ is the blackbody function. As the radiation flows out of the atmosphere, $S_\nu$ has the features of the opacity imposed on it. Therefore, edges may be introduced to the spectrum corresponding to the sharp changes in the continuous absorption coefficient – in the visible regime, this produces the Balmer discontinuity at 3647 Å for hotter stars. These features are illustrated in Figure 5, where two examples of the spectrum produced from model atmospheres are shown: the dashed lines are the blackbody

![Figure 4](image1.png)

**Figure 4** The continuous opacity coefficient for three temperatures. The dotted line corresponds to atomic hydrogen bound–free transitions, the short dashed line to $\text{H}^-$ free–free absorption and the long dashed line to $\text{H}^-$ bound–free absorptions. The solid line is the total of the three absorption coefficients.

![Figure 5](image2.png)

**Figure 5** Influence of the opacity on the resultant spectrum: the dotted line is the absorption coefficient of Figure 4 for reference and the dashed line is the blackbody emission at the temperature of the star scaled by $\sim 1.1$ for clarity. The solid lines are spectra calculated from model atmospheres. Note the effect of the different total opacity on the resultant spectrum, e.g. the obvious Balmer discontinuity at 3647 Å for the $8000 \text{K}$ star is not present for the $5500 \text{K}$ star.
spectra for the same temperatures as the models – note that the large Balmer discontinuity for the hotter star is negligible for the cooler star, which is a direct by-product of the opacity (denoted by the dotted lines in Figure 5).

In fact, the size of the Balmer discontinuity can be used to measure the temperature of the star. At temperatures greater than about 9000 K, the ratio of the opacity on each side of the discontinuity becomes proportional to the number of hydrogen atoms in the second and third quantum levels. This is governed by the Boltzmann equation, which is only a function of temperature. For other ranges of temperatures, the size of the discontinuity depends on both the electron density and temperature.

2.9 Formation of Spectral Lines

The continuous spectrum is useful for determining several parameters about the star, most notably the temperature. More detailed information can be obtained from examining features caused by bound–bound transitions in the atmosphere – the spectral lines.

The lines correspond to significant increases in the opacity over a very limited frequency range. As the photosphere is always defined at an optical depth of $\tau_v = \frac{2}{3}$, then the photosphere for the lines is physically higher up in the atmosphere, and so the source function $S_r$ is less. An increase in opacity and a decrease in source function lead to a net decrease in intensity, and so the lines formed in the photosphere are always seen as absorption lines (i.e. the line intensity is less than the continuum on either side). This is illustrated schematically in Figure 6(a–c). In cooler stars the generation of the chromosphere and corona due to magnetic field lines reconnecting lead to an emission line spectrum containing lines from (possibly highly) ionized ions. This is because at high temperatures the line source function is large (although the continuum source function is small – in this case the chromospheric and coronal gas is definitely not in thermal equilibrium) and hence there is a net increase in intensity, thereby producing an emission line.

2.10 A Return to Real Spectra

Let us now return to the spectra shown in Figure 2 and point out some of the features which have been described. For the hot stars, the spectrum rises toward low wavelengths, until a maximum is reached. The hydrogen lines are particularly obvious for these stars. Neutral helium lines appear at 5015, 5875 and 6678 Å. The Na I (neutral sodium) line at 5889 Å is particularly visible for the cooler stars, as is a magnesium line at 5183 Å. Neutral calcium lines appear at 4426, 5588 and 6162 Å. Cooler
stars have many more lines, giving the spectra a more “ragged” appearance. For the lowest-temperature stars the hydrogen lines finally come into emission – a sign of the active chromosphere region.

Owing to their temperatures, the cooler stars may form molecules in their atmospheres. The spectra of the cooler stars readily display evidence for molecules – wide absorption bands created by TiO are clearly visible.

3 SPECTRAL LINES

Aside from being useful in determining what elements are present in the star’s atmosphere and what ionization states they are in, spectral lines offer a practical way of determining other parameters of the star through their line shape. At a first glance the lines should be infinitely thin as they are produced by electrons jumping from one set of quantum numbers to another – a transition which has a precise value of energy. However, there are several ways in which the line is broadened, or possibly split into several components. These include the natural width and also Stark and Zeeman splitting, although for most stars the line shapes are dominated by the Doppler effect. We must be aware, however, that although the shapes of spectral lines can in principle produce a lot of information, there is also the intrinsic broadening of the spectrograph to consider. This instrumental broadening is always present in measured spectra, and must be taken into account in interpreting line shapes – any intrinsic line shape is convolved with the instrumental line shape.

3.1 Natural Width

Classically, the electron–nucleus system is seen as an oscillator. When the electron emits radiation the oscillator is damped, and hence there is a small spread of energies with which the photon can emerge. This leads to the Lorentzian (or damping) profile (Equation 9):

$$
\phi_L \propto \frac{\gamma/4\pi}{(v-v_0)^2 + (\gamma/4\pi)^2}
$$

where $v_0$ is the central wavelength, $\gamma = 8\pi^2 e^2 v_0^2 / 3mc^3$ is the damping constant, $e$ is the electronic charge and $c$ is the speed of light.

A quantum description of the natural width uses Heisenberg’s uncertainty principle, $\Delta E \Delta t \approx \hbar$, where $\Delta t$ is the typical time an electron is in a given excited state and $\Delta E$ is the energy uncertainty. If a line has a large transition probability, then $\Delta t$ is small, leading to a large $\Delta E$, and the line is broadened. This quantum approach, of course, leads to the same line shape from the classical approach, and the profile is shown as a dashed line in Figure 7. The half-width in frequency characterizing the profile is $\delta \nu = \gamma / 4\pi$. More usefully, this corresponds to a wavelength natural half-width (which is independent of wavelength) of $\delta \lambda_N = 1.2 \times 10^{-4}$ Å.

3.2 Thermal Broadening

The atoms in the atmosphere are moving owing to their thermal energy – their number distribution with velocity is Maxwellian. The typical thermal velocity for an element with mass number $A$ is $v_0 = \sqrt{2RT/A}$, where $R$ is the gas constant and $T$ is the temperature. Some of the emitting atoms/ions will be moving toward the observer and some away with a velocity $v$, leading to a shift in frequency due to the Doppler effect of $\Delta \nu / v_0 = \pm v/c$ (the positive/negative sign corresponds to atoms moving toward/away from the observer).

When the Maxwellian distribution of velocities is considered, an infinitely thin line is broadened into the “Doppler” profile (Equation 10):

$$
\phi_D \propto \frac{1}{\Delta \nu_D} \exp -\left(\frac{v-v_0}{\Delta \nu_D}\right)^2
$$

where $\Delta \nu_D = v_0 \gamma / c$ is the typical thermal width (the combined effect of natural and thermal broadening are discussed below). This profile is shown as a dotted line in Figure 7.

As the line is formed at different geometric depths on the photosphere, the temperature of the atoms contributing to the line also varies. This mimics an additional random velocity component to the line and is called microturbulence (note that this is strictly a misnomer, as this effect is not really caused by turbulence). Also, it is possible that the optical depth of the line is less than $t_\nu = \frac{1}{2}$ in convective regions (see Figure 3a–d). In this case the photosphere may be formed in a convective region, and assuming that the motions have a

![Figure 7](image-url)

Figure 7 Doppler (dotted line) and Lorentzian or damping (dashed line) line profiles. The solid lines are the Voigt line profile formed from a convolution of the Doppler and Lorentzian profiles for values of the ratio of half-widths of the Lorentzian to Doppler profiles of $\alpha = 0.1$ and $\alpha = 0.5$. 

velocity distribution similar to the distribution of thermal velocities then they may be treated in exactly the same way as thermal broadening. These random convective motions are called macroturbulence. They can be included in the line profile in a particularly simple fashion – the typical velocity dispersion \( \nu^2 \) in the line profile is increased by summing the component velocity dispersions, \( \nu^2 = \nu^2_{\text{th}} + \nu^2_{\text{micro}} + \nu^2_{\text{macro}} \), where \( \nu_{\text{micro}} \) and \( \nu_{\text{macro}} \) are the velocities characterizing the micro- and macroturbulence, respectively and \( \nu_{\text{th}} \) is the thermal velocity.

As an estimate of the typical Doppler widths of lines, consider a gas at a temperature of 6000 K. The thermal velocity of hydrogen is about 10 km s\(^{-1} \). At the first hydrogen Balmer line at a wavelength of 6563 Å (denoted as H\(_{\alpha}\)), this velocity corresponds to a wavelength Doppler half-width of \( \delta \lambda_{\Delta \nu} = v_\text{th} \lambda / c = 0.22 \) Å, which clearly dominates over the natural width. Both macro- and microturbulent velocities are found to be of the order of a few kilometers per second, making the thermal motions most important in line broadening for hydrogen. However, for higher-mass elements such as iron (\( A = 56 \)), then the thermal speeds are 1.6 km s\(^{-1} \) and consequently the macroturbulence may be dominant.

### 3.3 The Voigt Line Profile

Both the natural width and the Doppler broadening should contribute to a typical line profile. In the middle regions of the line where the energy is only slightly different from the central energy, the damping of the oscillator is small and the line is dominated by the Doppler profile. Toward the edges of the line (the wings), the damping may become dominant over the Doppler broadening and so the line follows the Lorentzian profile. The final profile is then a convolution of the two profiles and is called the Voigt profile \( \phi_V \). Two examples are given as solid lines in Figure 7 corresponding to ratios of half-widths of 0.1 and 0.5.

### 3.4 Pressure Broadening

A line may be broadened by the effects of pressure. The two effects which are important here are collisional broadening and Stark broadening.

#### 3.4.1 Collisional Broadening

An atom in an excited state can be influenced by another passing atom. If the timescale for a “collision” is small compared with the natural lifetime of the excited atom, then it can de-excite sooner than it would have done in isolation. This reduces \( \Delta E \) in the quantum picture leading to a larger \( \Delta E \). Therefore, this collisional de-excitation will broaden the shape of the line in exactly the same way as broadening does – the damping constant \( \gamma \) of Equation (9) is increased. The amount of broadening is dependent on the natural lifetime (given by the inverse of the Einstein \( A_j \) coefficient for a given line, where \( i \) and \( j \) are the two levels, \( j \) the higher), and the collisional de-excitation rate \( R_i = 8.65 \times 10^{-12} n_e \Omega_{ij} / T_e^{1/2} g_j \) s\(^{-1} \), where \( n_e \) and \( T_e \) are the electron density and temperature respectively, \( g_j \) is the statistical weight of level \( j \) and \( \Omega_{ij} \) is the collision strength which is a constant for a given transition. If there are \( \Gamma \) transitions per second caused by collisions, then the effective damping constant \( \gamma_{\text{eff}} = \gamma + \Gamma \). However, this form of collisional broadening is often masked by the Doppler effect, described above.

#### 3.4.2 Stark Broadening

When an atom or ion is subjected to an electric field, small changes are induced in the excitation levels of the atom or ion. This is the Stark effect, which can lead to extra broadening of the lines. When the atmospheric pressure is large, the weak electric fields around ions slightly change neighboring atoms’/ions’ emission frequencies. In the quantum picture, the change in excitation energies shortens the lifetime of electrons in these levels and leads naturally to a larger \( \Delta E \) owing to the uncertainty principle. The effect depends upon proximity of ions and is described as the “molecular” Stark effect (again this is a misnomer, as molecules are not necessarily involved: the name differentiates it from the Stark effect in a large-scale electric field). The line broadening generated by the molecular Stark effect is exactly the same in form to the Lorentzian profile, and produces its own constant \( \gamma_S \) characterizing the broadening. The change in energy induced by a close perturber on the transition between two levels is \( \Delta E \propto R^{-m} \), where the integer \( m \) describes the type of interaction and \( R \) is the distance to the perturber. If the energy change is linearly dependent on the applied electric field \( E \), then \( \Delta E \propto E \propto \epsilon / R^2 \), and hence \( m = 2 \) corresponds to linear Stark effect. The perturber is most likely to be a proton or an electron for \( m = 2 \) (this has most effect on hydrogen lines), electrons for \( m = 4 \) (the quadratic Stark effect, which may be important for hot stars) and neutral hydrogen for \( m = 6 \) (Van der Waals effect, which is more important for cool stars). The energy change corresponds to a shift in frequency of \( \Delta \nu = C_m R^{-m} \), where \( C_m \) is a constant dependent on the type of effect.

Calculations and measurements for the values of \( C_m \) are difficult and indeed well known for only a few simple atoms. For the linear Stark effect in the case of large field strengths, an analytical expression for the opacity as a function of wavelength in the line wings may be derived (Equation 11):

\[
\phi_S = \frac{C_m^{3/2} \epsilon}{(\lambda - \lambda_0)^{3/2}}
\]
where $\mathcal{E}_0$ is the typical field strength defined as the electronic charge divided by the square of the mean interparticle separation $r$ (Equation 12):

$$\mathcal{E}_0 = \frac{e}{r^2} = e \left(\frac{4\pi n}{3}\right)^{2/3}$$

where $n$ is the number density of particles. The values of $C$ in this expression vary for each line – for the hydrogen Balmer series, $\text{H}_\alpha$ 6563 Å, $C = 3.13 \times 10^{-16}$; $\text{H}_\beta$ 4861 Å, $C = 0.89 \times 10^{-16}$; $\text{H}_\gamma$ 4340 Å, $C = 0.44 \times 10^{-16}$; $\text{H}_\delta$ 4101 Å, $C = 0.31 \times 10^{-16}$. This broadening of lines can be seen in Figure 8, where the Balmer series of hydrogen lines for three hot stars (of similar temperature at $\sim 25,000$ K) are plotted. The continuum variation has been divided out of the spectra so that a direct comparison of the lines can be made. The bottom line corresponds to a main-sequence star which has a high pressure in the atmosphere, the middle line to a giant star and the top line to a supergiant star which has low pressure in the atmosphere.

Another effect of an electric field is the lifting of the energy degeneracy of the levels. This should produce several broadened lines for each transition, which blend into each other. For hydrogen the degeneracy increases with principal quantum number $n$, although the energy differences decrease as $1/n^3$. Therefore, the effects should be more noticeable in higher transitions (i.e. it will affect $\text{H}_\gamma$ more than $\text{H}_\beta$ and $\text{H}_\alpha$). At some $n$ the broadening of the lines becomes larger than the differences in the lines themselves and the hydrogen lines blend into each other (this can be easily seen in Figure 8). This provides a method of measuring electron pressure – the upper level $n_u$ where the lines blend is related to the electron density $n_e$ via $\log n_e = 23.26 - 7.5 \log n_u$.

### 3.5 Zeeman Splitting

The Zeeman effect occurs when the emitting gas is in a magnetic field. The spin of the electron and the magnetic moment of the orbital interact with the magnetic field, and the energy degeneracy of the quantum state is lifted. Therefore, there exists a splitting of the previously degenerate energy levels and instead of a single component, three components are seen (corresponding to different magnetic quantum numbers). The central component, at a wavelength unaffected by the magnetic field, is denoted as the $\pi$ component, whilst the two other components are denoted $\sigma^+$ and $\sigma^-$ for the higher and lower energy (corresponding to longer and shorter wavelengths, respectively). The degree of separation between the $\pi$ and $\sigma$ components is given by Equation (13):

$$\Delta \lambda_Z = 4.7 \times 10^{-9} \lambda^2 B$$

where $B$ is the magnetic field strength measured in tesla and $\lambda$ is measured in angstroms.

Magnetic fields vary widely in stars – in main-sequence stars $B$ may be as large as 1 T for the most magnetically active stars, whereas for white dwarf stars fields of up to $10^4$ T have been found [although the majority of white dwarfs (~96%) have not been observed to have any magnetic effects]. Therefore, Zeeman splitting will be negligible in most stars, and it is only clearly detectable in some white dwarf stars. We should note that magnetic fields may produce other features in the radio spectrum (see section 6.1). Figure 9 shows an example of Zeeman splitting of the hydrogen lines in the star PG 2329+267, which has a total magnetic field strength of ~230 T (these observations can only measure the line-of-sight magnetic field, which is around 160 T for this star). Note also in Figure 9 the very wide Stark broadened wings of the hydrogen lines.

### 3.6 Velocity Fields

The velocity fields we have dealt with so far are coherent only over a small part of the star, and hence we have assessed their broadening effect by assuming that motions are uncorrelated and are distributed in a Gaussian fashion about a mean of zero. However, there are velocity fields which are coherent over scale lengths similar to the physical size of the star which have to be taken into account. The first of these is stellar rotation. All stars rotate at some level, and rotation velocities up to the breakup velocity (where the centripetal effects of rotation and gravity balance and so the gas becomes unbound, and the star breaks up) have been observed.

Rotation affects the line profile by Doppler shifting parts of the star – some are approaching the observer.
Figure 9 Example of Zeeman splitting of hydrogen lines. The top spectrum is a non-magnetic white dwarf star (WD 1344 + 572). The lower spectrum is for the magnetic white dwarf star PG 2329 + 267 which has a magnetic field of 230 Tesla. The region around Hβ 4681 Å has been expanded to display the Zeeman splitting, showing the line profile for PG 2329 + 267 (solid line) with the reference line profile of WD 1344 + 572 (dotted lines) shifted as if it had the same magnetic field to illustrate how the Zeeman split line profile is built up.

and some are receding, and hence the effect is symmetric about the line center. Because of the coherent nature of the rotation, we cannot simply add another velocity component to the Doppler profile, but must convolve the Doppler/Voigt profile with the profile characteristic of rotation.

The rotation profile as a function of wavelength is given by Equation (14):

$$ R = \frac{(2 - \varepsilon)[1 - (\lambda - \lambda_0)^2/\Delta\lambda^2]^{1/2}}{\pi \Delta\lambda (1 - \varepsilon/3)} $$

where $\varepsilon$ is a coefficient of order unity describing the variation of angle of incidence of the observer to the atmosphere across the observed hemispherical surface of the star. $\Delta\lambda$ is the wavelength shift corresponding to the projected rotational velocity at the equator ($v \sin i$, where $v$ is the equatorial velocity and $i$ is the angle from the polar axis to the line of sight). This profile is shown with examples of observed lines in Figure 10. Often the rotation velocity of a star is large enough to dominate over most of the line profile.

Figure 10 Rotational profile and examples for the He I 4921 Å line. In (a), three profiles have been calculated. These have $\Delta\lambda = 5$ Å (dotted line), 3 Å (dashed line) and 1 Å (solid line), which correspond to projected rotational velocities $v \sin i$ of 300, 180 and 60 km s$^{-1}$, respectively. In (b), the He I 4921 Å line profile for two stars is presented (squares): HD 209975 has a projected rotational velocity of $\sim 30$ km s$^{-1}$ and HD 219 668 has $v \sin i = 300$ km s$^{-1}$. The solid lines are the rotational profiles given in Equation (15) and the dotted profiles are the rotational profile convolved with the instrumental line broadening of $\sim 1.5$ Å.
Other velocity fields may be present around stars owing to the accelerating winds that they may possess. These winds have no effect on the photospheric lines as in general they are diffuse flows. However, some lines may be particularly affected by the flow – for example, in hot stars some carbon, nitrogen and silicon lines in the UV region can display characteristic profiles of winds (see section 6.4).

4 PRACTICAL TECHNIQUES

4.1 Instrumentation

To obtain a spectrum of an astronomical source requires three basic components: a telescope, a spectrograph and a detector. The telescope is responsible for collecting photons from the source and bringing them to a focus. An aperture placed at this focus admits light into the spectrograph, which disperses the light. The resulting spectrum is then imaged by a detector, usually some form of array such as a charged-coupled device (CCD).

A long slit is used as the entrance aperture and the spectrograph and detector array are correctly oriented, then the resulting spectrum will be dispersed along one detector axis in wavelength. The other axis will reflect the spatial distribution of the incoming light along the slit.

The fundamental parameter defining an astronomical spectrograph is the resolving power $R$, defined according to Equation (15):

$$ R = \frac{\lambda}{\delta \lambda} \quad (15) $$

where $\lambda$ is the central wavelength and $\delta \lambda$ the resolution (roughly defined as the minimum resolvable separation of two spectral lines). As a general rule, increasing $R$ will decrease the sensitivity of the instrument as the light will be dispersed over a greater physical area.

We conventionally divide spectrographs into three resolution ranges, low, medium and high. Low-resolution spectrographs have $R < 1000$ – they are designed for high efficiency, often using all transmission optics (i.e. no reflection) and are therefore most useful for observing very faint objects. Medium-resolution spectrographs have $R \approx 1000–10000$ and typically use reflecting optics. Their resolution is sufficient to allow spectral classification using the Morgan and Keenan (MK) system (see section 5.1) and radial velocity determinations for binary systems. High-resolution spectrographs, with $R > 10000–100000$, often use a cross-dispersed, échelle design in order to obtain a wide wavelength coverage at high resolution. However, because of their complicated optics and high dispersion, their sensitivity limits them to relatively bright objects.

4.2 Data Acquisition

The exact observing procedure followed to obtain a fully calibrated spectrum of an astronomical source naturally varies from instrument to instrument, and also depends on the reason for obtaining the spectrum. For instance, for some applications (e.g. radial velocity determinations) a precise wavelength calibration is vital, whereas for others (e.g. spectral classification) it is not. In this section we therefore simply give a generic overview of the procedure, assuming our aim is to obtain a wavelength and flux (intensity) calibrated spectrum of a star.

The first task in taking a stellar spectrum is, of course, to acquire the object on to the spectrograph slit (which has a typical projected width on the sky of ~1 arcsec). For bright objects a slit-viewing television camera can be used to see the reflection off the slit jaws of the telescope image, and the telescope pointing adjusted to place the object of interest on the slit. For faint objects which cannot be directly viewed, a blind offset procedure must be used, i.e. the slit-viewing camera is used to align the telescope on a nearby bright star, and then a precise offset to the telescope coordinates is applied. When observing objects close to the horizon (i.e. through a thick layer of the Earth’s atmosphere), we must be aware of the effect of differential atmospheric refraction. The difference in refractive indices for red and blue light in air can cause a significant shift in the apparent position of the object in the sky between these colors which can be enough to move the object out of the slit at one end of the spectrum. In order to counter this effect, many astronomical spectrographs have the ability to rotate the slit so that it can be aligned so that it runs parallel to the direction of refraction (i.e. perpendicular to the horizon) at any given sky position.

Once we have taken an exposure of the spectrum, it needs to be corrected for several aberrations due to the detector itself, the spectrometer and the effect of the Earth’s atmosphere. First the spectrum must be calibrated in wavelength so that we know exactly which wavelength corresponds to which pixels of the CCD image. This uses the traditional spectroscopic approach of using arc lines to provide wavelength references, typically CuAr or CuNe. Because of the extreme faintness of many stellar spectra, it is not feasible to expose the arc lines and source simultaneously on the detector. Therefore, an arc calibration image is usually obtained both before and after the source exposure (the two arc exposures allowing calibration of any flexing of the spectrometer due to the changing gravity vector as the telescope tracks the source across the sky.)

Next we consider removing the signature of the detector from the data. The first effect we must consider is the removal of small-scale, pixel-to-pixel variations in
detector sensitivity. We do this by constructing a so called “lamp-flat” – effectively a map of these variations which we can divide into our image. This is obtained by observing a tungsten lamp (which has a smooth, blackbody-like spectrum) mounted to shine on to the entrance slit. However, because the tungsten lamp light path is not the same as that followed by light coming through the telescope from the star, the lamp-flat does not accurately reflect the large-scale spatial sensitivity variations across the detector array. To map these, we must observe a “sky-flat” at twilight by placing the slit over a blank area of sky that is relatively bright. This sky-flat can then be collapsed in the wavelength direction to make an overall map of the spatial variation. In turn this is then divided into the lamp-flats to produce a master flat-field which can be divided into an image to remove the spatial and small-scale wavelength sensitivity variations.

Finally, we must consider removing the large-scale wavelength sensitivity variation from the spectrum. In the visible wavelength regime this is caused mainly by the dependence of the quantum efficiency of the detector on wavelength, i.e. the responsivity of the detector is not constant over the wavelength range over which it is used. However, in the near-infrared (NIR) region (λ = 1–20 µm) it is dominated by the strongly wavelength-dependent water vapor absorption of the Earth’s atmosphere. The variation can be eliminated by observing a “standard star” which has a well known spectrum. Dividing the observed standard star spectrum by its actual spectrum yields a pixel-to-pixel correction curve.

This may then be divided into the observed spectrum of the source in which we are interested to produce its “real” spectrum, which is wavelength calibrated and free of aberrations produced by the spectrometer and detector. However, we should note that we are not only observing the star, but also the night sky around the star. The spectrum will therefore contain contaminating telluric “sky” emission lines (mainly caused by OH airglow in the upper atmosphere), which can be removed by extracting a sky region (i.e. one devoid of object flux) from the image of the same size as the object region and subtracting the resulting sky spectrum from the object spectrum. Finally, we are left with a spectrum of the object star itself free from any aberration (although residual errors introduced by the photon noise in the object and sky and the noise characteristics of the detector will still remain in the spectrum).

4.3 Line Identification

Spectral line identification may be carried out using either laboratory or stellar line lists. These traditionally group species in terms of multiplets, with the relative strengths of the components given. This means that if a line is suspected to be due to a certain species, the identification can be confirmed by searching for the other components of the multiplet in the spectrum and checking that they have the appropriate strengths. We note here that astronomers have a “nonstandard” method of referring to the ionization state of atoms and ions. In this method, neutral species (i.e. atoms) are indicated by the appropriate chemical symbol, followed by the small roman numeral I. Therefore, neutral hydrogen is referred to as H_I, and neutral oxygen by O_I, Ionized species are referred to by a roman numeral suffix with the value of one more than the ionization state. Therefore, singly ionized helium (He^+) is referred to in the astronomical literature as HeII and triply ionized nitrogen (N^3+) as NIV.

5 BASIC CHARACTERIZATION OF STARS

5.1 Spectral Classification

Spectral classification is a fast and efficient tool for deriving the basic parameters (luminosity and surface temperature) of stars. Classically, it is based on a “by eye” comparison of the strength and width of spectral features between the object of unknown spectral type and spectra of stars of known spectral type (“spectral standards”). Alternatively, the comparison can be carried out by computer using minimization techniques. Also, the spectral type of a star may be found by taking broad-band observations – the most common scheme for doing this uses three filters covering the visible spectrum: U (UV) from 3000 to 4000 Å, B (blue) from 3800 to 5200 Å and V (visible, yellow–green) from 4800 to 6200 Å. Comparison of the flux ratios in these filters to spectral standards provides the spectral type – essentially this is very crude spectroscopy.

The primary reference source for comparison stars is the MK list of standards. The MK classification scheme classifies spectra on the relative strengths of lines to yield a “spectral class” and on the widths of those lines to yield a “luminosity class”. The core MK spectral classes are O, B, A, F, G, K and M. Each of these is nominally divided into 10 subclasses which are indicated by arabic numerals, e.g. a B2 star is closer to an O star than it is to a B7 star. The main observational characteristics of each spectral class are given in Table 2. From the table, it is clear that species with high ionization and excitation potentials dominate the so called early (O–B) spectral classes, indicating that the temperature in their photosphere is large. In contrast the late (K–M) spectral classes show lines of neutral atoms and molecules, indicating a much lower temperature (see Figure 2).

In section 3.4 we demonstrated that the width of photospheric absorption lines is affected by pressure broadening, with broader lines indicating higher pressure
and hence surface gravity. As we have seen in section 1, there is a linear relationship between the luminosity of a star $L$ and its surface area $A = 4\pi R^2$ (where $R$ is the star’s radius), i.e. $L = 4\pi R^2 c T_{\text{eff}}^4$. Also, there is an inverse proportionality between the acceleration due to gravity at its surface (surface gravity) and radius, $g = GM/R^2$, where $M$ is the star’s mass. Therefore, it is apparent that a more luminous star of a given effective temperature will have a lower surface gravity and hence pressure. Consequently, the photospheric lines in a more luminous star will be affected less by pressure broadening than a less luminous star, as illustrated in Figure 8. We can therefore use the width of the photospheric lines in a spectrum to derive the “luminosity class” of a star which is denoted by a roman numeral suffix to the spectral class (see Table 3).

The combination of spectral class and luminosity class is often called a “spectral type”, and gives a fairly complete description of the nature of a star (Table 4). The spectral class fixes the temperature and the luminosity class fixes the luminosity.

5.2 Abundance Analysis

Spectral classification gives us a good idea of the physical conditions in the photosphere of the star. However, if we wish to determine the chemical abundances of different species in the photosphere, we must use more quantitative techniques. The basic method employed for this determination is the “curve of growth” method. For very high precision work this can be supplemented by “spectral synthesis”, where computed model atmosphere grids with differing abundances and photospheric conditions can be used to generate artificial spectra for comparison with the observed spectrum. However, in many cases the curve of growth method gives a sufficiently good determination and is much quicker to carry out.

strong emission lines of hydrogen in its spectrum, and therefore has the spectral type B0Ve. Also for close binary systems a composite spectrum of both components may be recorded, in which case the two spectral types are given joined by a + symbol (e.g. B5V + F7III).
To apply any quantitative method we must first have a technique for measuring the strength of absorption lines. The standard measure of the strength of a spectral line is the “equivalent width” (W). As the name suggests, this defines the strength of a line as equal to the equivalent width of nearby continuum that contains the same total flux as the line (see Figure 11). W is independent of spectral resolution and absolute flux calibration, and therefore provides a simple, instrument-independent measure of line strengths.

We must now ask how W varies in proportion to the line absorption coefficient (k_L), which for a given species will be proportional to the abundance (N, the number density of the species). First we consider the case where k_L ≪ k_C (the continuum absorption coefficient). The line width will be governed by the core of the Voigt profile, i.e. by the thermal properties of the atmosphere (and therefore will be independent of N), although the line depth will be proportional to k_L, and so W will be proportional to k_L/N. Therefore, for these “weak” lines there is a linear relationship between N and W.

Now consider the case where k_L ≈ k_C. The line width will still be governed by the core of the Voigt profile (i.e. is effectively constant), but many of the photons in the line are being scattered or absorbed, and so the line will appear dark, i.e. there are no photons there – this is termed saturation. Therefore, the line depth is constant and so increasing N has no effect on W and we cannot determine abundances for such lines.

Finally, we consider the case of very strong lines where k_L ≫ k_C. In this case, while the line depth is still saturated, the damping wings of the Voigt profile start to become significant. It can be shown that the strength of the wings is proportional to \( \sqrt{N} \), and therefore W is proportional to \( \sqrt{N} \).

Combining these three cases together, we can produce a “curve of growth”, showing how W varies with Nf (where f is the line oscillator strength) (see Figure 12). To use the curve of growth to determine the abundance of a species, we plot the observed values of log W for the various transitions of the species versus log f for each transition. The resulting observed curve of growth can then be compared with the theoretical curve by sliding it along the log Nf axis. When the two curves overlap, log N can be determined by the offset between the two graphs.

We note here that it is traditional in astrophysics to measure abundances relative to the solar hydrogen abundance, which is set at log N_D^12:00. For example, on this scale the solar Li abundance is log N_Li:7 by number, i.e. a factor of 10^{11.3} smaller. In Table 6 the abundances of the elements are given for the Sun.

5.3 Radial Velocity Analysis

Additional information about the nature of a star can often be obtained by measuring the central wavelengths of the lines. Until now we have considered that the line profiles are symmetric about the central wavelength, although we must examine the case when the star is moving relatively with respect to us. In this case we can measure the radial velocity of the star (in a few cases the tangential velocities of stars can be measured directly). For a many-lined spectrum this is best achieved by using a cross-correlation technique to compare with radial velocity standards. The offsets of the lines from the rest wavelengths that are measured can be converted to velocities using the Doppler equation (Equation 16):

\[
\frac{v}{c} = \frac{\Delta \lambda}{\lambda_0}
\]

where c is the speed of light, \( \Delta \lambda \) the Doppler shift and \( \lambda_0 \) the rest wavelength of the line.

These radial velocities can often tell us much about a star. In combination with the object’s position in the sky,
they allow us to make an estimate of the distance to the object (by comparison with the rotational distribution of stars in the galaxy). This also allows estimates to be made of the age and chemical composition of the object, by comparing it with stars in a similar physical position. Many stars show variable radial velocities. This can indicate that the star is in a binary system, in which case monitoring the velocity variations over an orbit allows an estimate of the ratio of masses of the two stars in the binary. Very precise radial velocity variation measurements (accuracy \(~1 \text{ m s}^{-1}\)) of nearby stars can in fact be used to detect extra-solar planets around some stars. Variable radial velocities may also indicate stellar pulsations in isolated stars as the atmosphere rises and falls – the analysis of the modes of these pulsations (astroseismology) can yield much important information about the interior structure of stars.

### 6 WAVELENGTH REGIMES

Our discussion has so far concentrated on optical spectroscopy (taken to imply a wavelength range of \(\lambda \approx 3000–10 000 \AA\)). However, it is possible to carry out spectroscopy at wavelengths ranging from the radio to \(\gamma\)-rays. The astrophysical processes occurring at these different wavelengths are often very different from those we have described as being responsible for the optical spectrum of the source, and therefore allow us to probe different regions of the stellar environment. Each wavelength regime also requires different detector technologies and observing techniques. Here, the Earth’s atmosphere has been a driving force; for example, at high frequencies it is completely opaque, and so space-borne telescopes have been necessary. This section provides a brief summary of both the techniques used and the physical processes involved for the wavelength regime.

#### 6.1 Radio Spectroscopy (Wavelength 200 \(\mu\text{m}\)–100 m)

At wavelengths longer than around 1 cm the Earth’s atmosphere is transparent to radio waves. These can be detected using radio telescopes (essentially a parabolic reflecting antenna which focuses incoming radio waves to a small pick-up antenna). The radio waves induce an electrical signal in the pick-up antenna that can be tuned using a resonant circuit and down-converted to a lower (intermediate) frequency (longer wavelength) using a heterodyne mixing technique. The intermediate frequency can then be demodulated and the resulting frequency spectrum digitized by computer. The smallest channel width available is usually \(\sim 128\) kHz, giving a spectral resolution at 5 GHz of \(R \approx 20000\).

Below wavelengths of \(\sim 2\) cm, the Earth’s atmosphere starts to become opaque, mainly owing to water vapor, but several “transparent” bands are available at wavelengths stretching down to \(\sim 350\) \(\mu\)m. At wavelengths below a few millimeters, traditional radio engineering techniques are no longer applicable owing to the extremely small size of the microwave circuitry required. Instead, bolometer arrays are employed that detect the heating effect of the incoming radiation. The use of filters allows a rough spectral discrimination, but only with a resolution \(R\) of \(<10\).

An important mechanism responsible for radio continuum emission is synchrotron radiation, i.e. that produced by accelerated electrons in a magnetic field. Accelerated electrons are produced in stellar sources such as some interacting binary stars and rapidly rotating remnant cores of supernovae – neutron stars (pulsars). The energy spectrum of the electrons is often characterized by a power law as is the emitted radio continuum spectrum. Maser action can produce line emission in radio spectra. For low-density regions such as those found in pre-main sequence objects and the outer atmospheres of cool supergiants, the population inversion necessary for maser emission can be created. In these regions the density is sufficiently low that a metastable level may become populated, the pumping mechanism being either

Abundances are expressed as logarithm of both number and mass abundance on a scale for which hydrogen is 12.00. (The data is from C.W. Allen, *Astrophysical Quantities* (see Further Reading list).)
radiation, collisions or even chemical. Molecules that can be excited in this way include OH, water vapor and CO.

Another process responsible for line features in radio spectra is line transitions between closely adjacent energy states. For example, neutral hydrogen (HI) demonstrates the famous 21.1 cm line due to a forbidden hyperfine transition involving the alignment of the electron and proton spins. Such transitions cannot occur in the relatively dense environment near a star owing to collisional de-excitation, but they can be superimposed on a stellar spectrum in the intervening interstellar medium between us and the star. The dynamics of the lines can be measured using their Doppler profiles and shifts, and so we can gain information on the diffuse interstellar gas in the galaxy.

6.2 Far-infrared Spectroscopy (Wavelength 20–200 µm)

Owing to the opacity and temperature of the Earth’s atmosphere in this region, satellite-based telescopes are required to explore the far-infrared (FIR) region. The basic optical design of FIR telescopes and instruments is similar to that in optical spectroscopy and detectors are typically based on exotic semiconductor hybrids, such as Ge:Ga and Si:B. However, the effect of the thermal environment of the optics is much more important than that for an optical telescope. Applying Wien’s displacement law, we see that blackbody emission peaking at 100 µm corresponds to a temperature of 20–30 K. Therefore, we must cool both the telescope and instrument to temperatures lower than this to prevent emission from the telescope completely dominating over the astronomical source. The recent Infrared Space Observatory (ISO) satellite has been the only infrared (IR) satellite capable of relatively high-resolution spectroscopy, giving resolutions between a few hundred and a few tens of thousands using two grating spectrometers.

The FIR region allows us to see relatively cool material such as dust and cool gas which may be in the process of forming stars, or may be part of a star’s ejecta as it dies. Often molecular and atomic features (e.g. CI 157 µm) can be observed in star-forming regions and premain sequence objects.

6.3 Near- and Mid-infrared Spectroscopy (Wavelength 1–20 µm)

Unlike FIR spectroscopy, NIR and mid-infrared (MIR) spectroscopy can be carried out from the ground, although it is best carried out from high, dry sites such as Mauna Kea, Hawaii, or Antarctica. Even at the best sites, however, continuous coverage of the region 1–20 µm is not possible from the ground. Rather, we can observe through a number of spectral windows, centered at 1.2, 1.6, 2.2, 3.5, 5, 10 and 20 µm where the atmosphere is transparent. Telescopes for IR use are designed in order to reduce their thermal emissivity, as a major contributor to the background at wavelengths > 2.5 µm is the thermal emission from the telescope.

Modern spectrographs for IR use are based on the use of cooled optics and gratings, and can be designed for spectral resolutions from a few hundreds to tens of thousands. Detection generally uses array detectors based on hybrid semiconductors such as InSb that must be cooled to around 35 K and have a rapid readout as the fast buildup of thermal charge within the arrays and the very bright sky background mean that exposure times must be kept short (typically <10 s at 2.2 µm, and only tens of milliseconds at 10 µm). Because the sky background can be much brighter in the IR region than the astronomical source, very accurate sky subtraction is vital. This is sometimes achieved by having a telescope secondary mirror that can be chopped on and off source at rates between 0.1 and 10 Hz depending on the observing wavelength. The physical processes giving rise to IR spectral features in stars are similar to those we have discussed for optical spectroscopy, although the dominant opacity sources are often very different. For instance, the optical spectra of M stars are dominated by TiO bands (see Figure 2) whereas in the region 1–2.5 µm the dominant opacity source is water vapor. An important feature in many IR spectra is a ~10 µm silicate feature that is seen in very cool objects and is a signature of dust formation in their atmospheres at temperatures of less than around 2000 K. In some cases an important advantage of NIR spectroscopy over optical is that IR photons suffer much lower interstellar absorption by dust grains than optical photons, and therefore using IR observations we can penetrate into dusty regions such as the center of our galaxy and star forming regions such as those in Taurus and Orion.

6.4 Ultraviolet Spectroscopy (Wavelength 100–3000 Å)

UV photons with wavelengths less than around 3000 Å are blocked by the Earth’s atmosphere and are therefore accessible only from satellites. At wavelengths above around 1000 Å, instrument and detector technologies similar to those employed for optical spectroscopy can be used. At wavelengths shorter than around 1000 Å, grazing incidence techniques such as those employed for X-ray telescopes (see below) must be employed.

In addition to normal photospheric lines, a key feature in many UV stellar spectra for stars of up to a few solar masses is strong, coronal emission lines (see section 2.4). These lines are typically of species with very high excitation energies (e.g. CIV 1545, NV 1238 and SiIV 1393 Å). Such lines are indicative of very high
temperatures up to 100,000 K, and the spectral energy distribution of the continuum emission indicates that the coronal temperature reaches over 10^6 K. For higher-mass stars exactly the same lines are present, indicative of ionization states higher than expected from the photospheric temperatures. These lines display very large Doppler shifts (>10^3 km s^{-1}) and have been successfully explained as a “wind” flowing from the star. The wind is driven by the radiation pressure from the large flux of high-energy UV photons being absorbed by line transitions in the gas.

6.5 High-energy Spectroscopy (Wavelength < 100 Å)

High-energy photons are usually labelled with their energy as opposed to their wavelength. The photon energy in electronvolts (eV) is related to its wavelength in meters by Equation (17):

\[ E = \frac{1.25 \times 10^{-6}}{\lambda} \quad (17) \]

There are two methods of differentiating an X-ray from a \(\gamma\)-ray: the first merely considers the energy \(E\) of the photons associated with the radiation. A simple definition might therefore be that photons of energy 0.1–100 keV are X-rays and higher-energy photons are \(\gamma\)-rays. This is somewhat arbitrary, however, and an alternative is to consider the origin of the radiation. By this definition, only nuclear processes give rise to \(\gamma\)-rays, whereas X-rays originate from radiation processes involving electrons.

X- and \(\gamma\)-radiation is blocked by the Earth’s atmosphere and, as for UV radiation, is accessible only via satellite experiments. A number of different technologies can be used to detect high-energy radiation. Owing to their penetrating nature, X-rays are naturally hard to focus, and grazing incidence techniques must be used to construct a telescope. The most commonly used detector for X-rays is the X-ray CCD, although position-sensitive gas proportional counters are also employed. Owing to the low count rates and large energy per photon (generating many photoelectrons per photon), X-ray CCDs can be read out continuously, allowing them to tag each arriving photon with an energy. It is therefore possible without a dispersive element to obtain some spectral resolution, typically \(R \approx 10–100\). To obtain higher resolutions a reflection grating spectrometer must be employed. For \(\gamma\)-rays, detectors may be based on the photoelectric effect, Compton scattering or pair production. Typical detectors achieve \(R \approx 10\) using a similar photon tagging mechanism to X-ray CCDs. Solid-state detectors based on high-purity germanium can increase the resolution to \(R \approx 300\). The principal processes that give rise to high-energy emission from stellar sources are (a) thermal emission from stellar coronae (see section 2.4), (b) accretion of stellar material on to a compact remnant of stellar evolution and (c) nuclear processes in supernovae (exploding massive stars). Stellar coronae have already been discussed and so we shall give a brief discussion of processes (b) and (c).

Accretion models are now accepted to explain the general properties of most strong stellar X-ray sources. These are considered to be binary stars (i.e. two objects orbiting around their common center of mass) in which one of the objects is a compact object produced at the end of stellar evolution (i.e. a white dwarf, a neutron star or a black hole) on to which mass is being transferred from the “normal” star. Accretion is a very efficient process at releasing gravitational potential energy. (Neutron star accretion will typically produce ~10^{16} J kg^{-1} of accreted material, whereas nuclear fusion of 1 kg of hydrogen to helium yields only ~5 \times 10^{14} J.) For neutron stars we expect photon energies in the range 1 keV–50 MeV, and observations show the resulting spectral energy distribution is generally well characterized as bremsstrahlung.

Spectral lines in accreting sources are generally due to one of two mechanisms. Lines such as the iron Kα line, which is often visible at around 6.7 keV, are produced by fluorescence as harder X-rays illuminate the in-falling material. Analysis of the shape and wavelength of such lines for relativistic distortions allows a determination of the geometry of the system and the nature of the central object. Second, cyclotron lines may be visible, indicating the presence of a strong magnetic field. This allows a determination of the magnetic field strength from the cyclotron line frequency (gyrofrequency) \(f_c\) (Equation 18):

\[ f_c = \frac{eB}{2\pi\gamma m_e} \quad (18) \]

where \(e\) is the electron charge, \(B\) the magnetic field density, \(m_e\) the electron mass and \(\gamma\) the relativistic gamma factor.

At the end of their lives, stars with masses larger than about 10 solar masses explode in a supernova, typically releasing about 10^{52} J in a couple of hundred days. We might expect them to be strong emitters of X- and \(\gamma\)-radiation owing to their extremely high luminosities and temperatures. However, supernovae are optically thick to high-energy emissions and the high-energy radiation is degraded to lower energies before the expansion of the supernova shell allows them to escape. The principal source of high-energy emission from young supernovae is from the radioactive decay from elements produced in the explosion. For example, 847 keV flux was detected from the supernova 1987A which was caused by the decay of Co^{56}, itself produced by the decay of Ni^{56}. The intensity and shape of the \(\gamma\)-ray line can be used to determine the mass of Ni^{56} synthesized in the explosion.
7 CONCLUSIONS – WHAT HAVE WE LEARNT?

We have found that stellar spectroscopy can be used to calculate the physical conditions of the atmospheric regions of the star. However, we have also seen that interpretation of spectra must be done in the framework of stellar structure and evolution. We have shown that stellar spectroscopy can provide more than temperatures and pressures – large- and small-scale velocity fields, ages of stars, circumstellar material and aspects of stellar structure may be detected and measured. There are some significant problems in obtaining spectra, from the intrinsic limiting resolution of the spectrograph to the problems of using satellite observatories for some wavelength regimes. As we cannot perform experiments on any star, then the study of stars in all wavebands is vital.

Using spectra, the theory of stellar evolution has been developed during the twentieth century and, although there are still unsolved problems, has largely been confirmed. It is fitting that the oldest branch of spectroscopy has been so successful as a tool for studying stars.

ACKNOWLEDGMENTS

The data plotted in Figure 1 comes from the Gliese catalogue (the nearest stars) and the Yale Bright Star Catalogue (the brightest stars). Dr Andy Newsam and Dr Tom Marsh are thanked for help in producing Figure 9. The model atmospheres spectra in Figure 5 were calculated by Dr R. Kurucz.

Dr Phil James is thanked for reading and making comments on the draft of this article.

FURTHER READING

There are many texts regarding the emission and analysis of stellar spectra. Here we list a few particularly relevant texts for the interested student.

Remote sensing from airborne and spaceborne platforms provides a means of mapping forest resources at a range of spatial scales. Local-scale mapping using aerial photography is a well-established technique for determining stocking density, forest cover and forest health over relatively small areas. Satellite remote sensing can be used to map forest resources over larger areas, including regional to global scales. Techniques have been developed to map forest species and forest cover using spectral and spatial information in remotely sensed images. This work has been extended to map key biophysical and biochemical properties such as leaf area index (LAI) and leaf nitrogen content. These data have been coupled with other information such as meteorological data to drive process-based ecosystem simulation models which may be used to monitor the production of forests and the rates of exchanges of energy and matter with the atmosphere and hydrosphere. Forests play a key role as a source of wood products but they are increasingly also being seen as playing a key role in the global climate system. Remote sensing is the only technique available to monitor forest resources at local, regional and global scales, and to develop an understanding of their role in the global ecosystem.

1 INTRODUCTION

The world's temperate forests occur as a broad belt across the Northern hemisphere between approximately 40 and 70° north with no equivalent biome in the southern hemisphere. The region is dominated by the evergreen coniferous Boreal forest which extends northwards to the Arctic tundra and southwards into temperate deciduous and mixed forest and, in drier areas, into steppe forest and the grasslands of central Eurasia and North America. The structure and composition of the forests vary greatly with climate and site conditions but within the region, the moist forests of northwestern North America have the highest biomass productivity of any forest area on Earth. From an economic point of view the conifer forests are important as a timber resource both for saw wood and for pulp wood. The mixed deciduous forests have historically also provided a valuable resource for building and for fuel, but their present distribution has been greatly affected by human activity, particularly in Western Europe and Asia. Continuous forest cover in these regions is generally restricted to areas which are not suitable for agriculture and, where forest cover is present, it is invariably secondary regrowth on areas which have previously been cleared.

Recent advances in modeling the fluxes of energy and nutrients in forest ecosystems have highlighted the importance of temperate forest ecosystems in the global climate system and in particular their role in the global carbon cycle. The Boreal forest covers some $15 \times 10^6 \text{km}^2$, represents approximately 21% of the forested land surface of the Earth and accounts for 13% of the carbon stored in the biomass and 43% of the carbon stored in the soil. These forests therefore represent an important terrestrial carbon "sink" and research has indicated that climatic warming may lead to significant changes in the carbon cycle and ecological functioning of the Boreal forest with feedbacks impacting on the global climate system. There are still great uncertainties about the size of the energy and carbon fluxes between the biosphere and the atmosphere but the analysis of time-series satellite imagery is beginning to provide relevant, reliable and spatially comprehensive data.

Information on temperate forest resources is required at a range of spatial and temporal scales from local...
forest inventories used for resource management purposes and updated annually, to global data on carbon, water and energy fluxes required for modeling climate change over a number of decades. Remote sensing instruments flown on aircraft and on satellites play a crucial role in providing the data to derive relevant forest resource information at all these scales.

2 BACKGROUND

Like all applications of remote sensing, the measurement of forest resources relies on the interaction of electromagnetic radiation with the surface and interpretation of the reflected (or emitted) signal. Optical sensor systems measure reflected radiation in one or more discrete wavebands located in the spectral range 400–3000 nm, whereas active synthetic aperture radar (SAR) systems measure backscattered microwave radiation at wavelengths between 1 and 1000 cm. Optical wavelengths are several orders of magnitude smaller than the leaves, needles and branches that make up a forest canopy and consequently radiation may be both absorbed and scattered by these components. In the case of the longer microwave wavelengths, scattering from leaves, branches, trunks and the ground is the dominant mechanism (Figure 1). It follows that optical remote sensing systems may provide information on the amount of foliage and its biochemical properties whereas microwave systems provide information on woody biomass and forest structure. In addition to potential information in the spectral reflectance signal, remote sensing instruments are imaging devices which may provide additional spatial information related to the three-dimensional structure of the canopy and the spatial resolution of the imaging sensor. (6)

The problem of extracting information on forest resources from remotely sensed data may be reduced to one of relating spectral, spatial and temporal variation in the data to variation in the biophysical and structural properties of the forest canopies. There is no direct physical relationship between the remotely sensed signal and the biophysical characteristics of the forest canopy, but the physical processes of scattering and absorption are controlled by the canopy characteristics. Extracting information on forest resources therefore depends on developing techniques to infer this information from the remotely sensed data. (7) The inference process may involve qualitative interpretation of imagery by a trained operator, the development of statistically based calibration equations or the use of mathematical modeling techniques.
3 MAPPING FOREST RESOURCES

Local-scale mapping of forest resources using aerial photography and ground-based field surveys remains important today, even with the availability of 1-m spatial resolution data from space. Manual air-photograph interpretation is required in applications which require the direct identification of tree species or an inventory based on surveying individual trees. Skilled air-photograph interpreters use qualitative properties of aerial photography, such as shape, pattern, tone and texture, to produce stock maps and forest inventory information, usually at scales of 1:25 000 to 1:5000. This work is generally coupled with surveys at ground level to measure directly wood volume, basal area and tree heights. Forest resource assessment by satellite remote sensing is unlikely to replace air-photograph interpretation at scales above 1:25 000, but where applications require maps of larger areas, the use of satellite images may enable the production of a cheaper and more consistent product.

The advantages of satellite sensor data for mapping forest areas have been recognized since the launch of the first civilian high-spatial resolution sensor, Landsat-1, in 1972. Thematic maps may be produced to show forest species, forest cover or forest condition. The procedure relies on the assumption that a given class (e.g. broadleaf forest) has a distinct and consistent spectral response or spectral signature. Most studies to date have used “traditional” supervised multispectral image classification techniques where areas of known class, or training areas, are defined a priori in an image and their spectral response quantified in terms of the reflectance mean and covariance between wavebands. Each pixel in the image is then classified according to its statistical probability of membership to a given class. Many studies have shown that this approach to mapping forest areas can be successful at a range of spatial scales from local, to regional and global. A weakness, however, is that the spatial information in the image data is not incorporated in the classification procedure and recent work has addressed this problem with the development of contextual classifiers which use both spectral and spatial characteristics of the imagery and evidential reasoning which allows data from different sources and at different scales to be incorporated.

The application of an artificial neural network (ANN) to remotely sensed land cover classification has also been an important recent development. An ANN involves the use of artificial intelligence techniques and provides a powerful tool to discriminate patterns in many different types of data. ANNs are particularly useful in classifying remotely sensed data because, unlike the traditional statistically based methods, they make no assumptions about the statistical distribution of the input data, can handle noisy data and can accommodate ancillary data from other sources. A number of studies have shown that land cover classification accuracy based on a neural network approach is higher than that based on statistical classifiers, particularly when the training data sets are small. Studies which have used ANNs to classify forest areas have reached similar conclusions.

4 OPTICAL REMOTE SENSING OF FOREST BIOPHYSICAL PROPERTIES

Although image classification methods may produce useful information on the location and spatial extent of forests, and descriptive information on forest type or species, they do not provide quantitative information about forest biophysical or structural properties. In fact, the spectral properties of all vegetation canopies is a function of these properties and information on canopy biophysical properties should therefore be accessible from remotely sensed measurements. Variables such as LAI, the one-sided area of leaves per unit ground area, and leaf biochemistry affect forest function in terms of light interception and absorption, nutrient cycling and productivity. They vary both spatially and temporally across forest areas and are difficult and expensive to measure. They are, however, the key spatial variables required to drive forest ecosystem simulation models at a range of spatial scales and so considerable effort has been expended in developing remote sensing techniques to map these variables over extensive forest areas.

4.1 Estimating Forest Biophysical Properties

Optical remote sensing has focused on the estimation of forest LAI or biomass and has built on earlier successful work to estimate these variables for agricultural crops and grassland canopies. At visible wavelengths light absorption is the dominant process and in general as LAI or biomass increase, visible reflectance decreases so that a negative asymptotic relationship between red reflectance (R) (600–700 nm) and LAI is expected. At near-infrared (NIR) wavelengths (700–900 nm) leaf absorption is low and leaf reflectance and transmittance are high. A positive asymptotic relationship is therefore expected between NIR reflectance and LAI or biomass. The spectral contrast between R and NIR reflectance has been used to develop “vegetation indices”, which are linear or non-linear combinations of the reflectance in two or more
wavebands and a number of studies have attempted to correlate vegetation indices with forest LAI.

Early studies by Peterson et al.\(^{27}\) and Spanner et al.\(^{28}\) examined the relationships between the LAI and reflectance of forest sites across the western United States. They found a significant negative relationship with R and a significant positive relationship with the simple ratio (SR) vegetation index (NIR/R) or normalized difference vegetation index (NDVI), but no significant relationship with NIR reflectance. Other studies have also found only weak correlations between forest LAI and the NDVI\(^{29,30}\) and it has been suggested that the spatially variable contribution of soil or understorey to the scene reflectance, coupled with variations in canopy structure and leaf optical properties, may confound the application of vegetation indices for estimating forest LAI.\(^{31}\) For example, Badwhar et al.\(^{32}\) found that the relationships between the LAI of aspen (Populus tremuloides) stands in Minnesota and R and NIR reflectance were seasonally variable and in August, when there was full canopy cover and a well-developed understorey vegetation layer, no significant relationships were found. Curran et al.\(^{33}\) found a positive relationship between the LAI of slash pine (Pinus elliottii) stands in Florida and the NDVI, although again the strength of the relationship varied seasonally because of changes in understorey LAI. Chen and Cihlar\(^{34}\) found that the relationship between the SR vegetation index derived from Landsat thematic mapper (TM) data and the LAI of a Boreal conifer forest was strongest in the late spring when the understorey vegetation was not fully developed. This work was followed up by a detailed study which examined the seasonal variation in the understorey reflectance of the stands and its impact on vegetation indices.\(^{35}\) In contrast to the findings of earlier studies, Fassnacht et al.\(^{36}\) found a strong positive relationship between LAI and NIR reflectance in Wisconsin. These studies together indicate that the strength of the relationships between forest LAI and vegetation indices such as the NDVI may be site, time and species specific and that above an LAI of about 5–6 the NDVI may not be sensitive to LAI variations. A number of authors have also suggested that the expected positive relationship between LAI and NIR reflectance may break down at higher levels of LAI because increased inter-canopy shadowing causes a decrease in NIR reflectance.\(^{17,26}\)

Recent research has sought to improve the estimation of forest LAI by the application of new vegetation indices based on either broad wavebands or high spectral resolution data from field spectrometers or airborne imaging spectrometers (AIS). Nemani et al.\(^{37}\) found that incorporating a middle-infrared (MIR) waveband with R and NIR normalized the effect of variable canopy cover on the relationship with LAI. The approach worked well at one test site but has yet to be evaluated for other forest environments. Foody et al.\(^{38}\) explored a number of different vegetation indices for mapping tropical forest biophysical properties and highlighted the potential of data in the 3–5 \(\mu\)m region of the MIR band which exhibited stronger correlations with the stand variables than the NDVI. High spectral resolution data, where measurements of surface radiance are made in several hundred narrow wavebands, have also been used to estimate forest LAI. Several experiments have shown that calculation of first or second derivatives of the canopy reflectance may suppress the effects of variation in understorey reflectance and allow more accurate estimation of LAI.\(^{39,40}\) High spectral resolution data may also be used to calculate the position of the “red edge”, the point of inflection in the reflectance spectrum round 720 nm. Correlations between the red-edge position and forest LAI have been found to be stronger than those with single wavebands or vegetation indices based on broad wavebands.\(^{30,41}\)

Significant advances have been made in estimating forest LAI from remotely sensed data and these have been partly facilitated by the use of new techniques and instruments for measuring the LAI of forest stands using light interception. This has allowed the traditional and expensive destructive sampling techniques to be complemented by techniques which allow rapid measurement of LAI at a large number of sites.\(^{42}\) Furthermore, large multidisciplinary experiments such as Oregon Transect Ecosystem Research (OTTER) and the Boreal Ecosystem and Atmosphere Study (BOREAS) have provided comprehensive ground and remotely sensed data sets with which to develop and test LAI estimation techniques.\(^{43,44}\) Further developments are likely to involve a greater emphasis on the application of radiative transfer models of forest canopy reflectance to investigate how differences in leaf optical properties and forest structure and composition affect the relationships between forest LAI and spectral reflectance.\(^{45}\)

### 4.2 Estimating Forest Biochemical Properties

Chlorophyll and water are the main chemicals in vegetation responsible for absorbing incoming radiation from the Sun. The characteristic spectral response of vegetation canopies is dominated by the broad absorption features of these two chemicals and it follows that canopy reflectance is closely related to their concentrations in the canopy. A number of studies have used remote sensing to estimate the chlorophyll and water content of forest canopies in investigations of forest damage caused by environmental stress and for inputs to ecological models. Riggs and Running\(^{46}\) attempted to detect water stress in conifer canopies using high spectral resolution data. However, they found that variation in canopy cover
between stands caused a larger variation in canopy reflectance than differences in water status. Dawson et al.,(45) related the ratio of reflectance at 970 nm to that at 900 nm, termed the water index (WI), to the water content of Boreal forest stands and found a weak negative correlation. They suggested that a priori knowledge of forest biophysical variables such as LAI may be necessary to determine accurately the canopy water content from remotely sensed data. Similar problems have been encountered in studies that have attempted to measure forest canopy chlorophyll content using remotely sensed data. (45, 48) The effects of variation in canopy cover and/or LAI on the relationships between forest canopy chlorophyll and water content is problematic area. However, Fourry and Baret,(49) have shown that if the canopy cover is high or can be considered constant, retrieval of these biochemical properties should be possible.

Pioneering work in the late 1980s began to explore the use of remote sensing for determining the relationships between other forest canopy biochemicals and rates and patterns of biogeochemical cycling (BGC). Ecologists had established the importance of foliar nitrogen content of forest vegetation which in conjunction with LAI is closely related to photosynthetic capacity and nitrogen uptake. (50) In addition, the ratio of leaf lignin to leaf nitrogen has been shown to be related to rates of litter decomposition. (51) Measurement of these and other biochemicals over large areas of forest was therefore seen as a key step toward mapping the spatial characteristics of forest nutrient cycles. (52)

The techniques of laboratory-based NIR reflectance spectroscopy were developed by analytical chemists in the 1950s for measuring the crude protein, dry matter, lignin and other biochemicals in dried ground vegetation samples. However, the application of these techniques in ecological remote sensing became possible only with the development of a new generation of field spectroradiometers and imaging spectrometers which allowed the measurement of surface reflectance in a large number of narrow wavebands. The leaf biochemicals of interest have fundamental absorption features in the 2500–15 000 nm region but also have overtone and combination absorption features in the 1100–2500 nm shortwave infrared reflectance (SWIR) region measured by many remote sensing instruments. The challenge for ecological remote sensing was to extend the laboratory techniques from analysis of dried ground samples to fresh leaves, whole branches and complete canopies.

Experiments on dried ground samples confirmed that leaf nitrogen and lignin content could be estimated using laboratory instruments. Wessman et al.,(53) collected samples of leaves and leaf litter from both deciduous and coniferous species. The samples were dried and ground and their reflectance measured using a laboratory spectrometer. Multiple linear regression was used to define calibration relationships between the first and second derivatives of reflectance and nitrogen and lignin content. The biochemicals were estimated with standard errors of 0.11 and 2.9%, respectively. Other studies provided similar results and also showed that the wavelengths selected by stepwise multiple regression techniques were close to known absorption features for a given leaf biochemical. (52, 54)

Extension of this work to fresh foliage further indicated the potential of the technique for estimating the biochemistry of intact leaves. (52) Although the presence of water in the leaves may suppress the biochemical signal because of water absorption in the SWIR region, several studies have shown that leaf nitrogen, protein, cellulose, lignin, chlorophyll and starch content may be estimated from reflectance measurements. (55– 57) It does appear, however, that the wavebands selected in stepwise regression for fresh leaves are not always clearly related to known absorption features for the biochemicals. Grossman et al.,(58) showed that band selection depended on whether the chemical data were expressed in terms of leaf concentration (grams per gram) or as leaf content (grams per square meter) and was also sensitive to the set of calibration samples used. They also highlighted the problem of overfitting where high coefficients of multiple determination \( r^2 \) were obtained for datasets produced by randomization of the measured data.

The results of the work on estimating leaf biochemistry stimulated experiments on estimating the biochemistry of complete forest canopies using data from imaging spectrometers. The first experiments were conducted using the AIS, which recorded a 32 × 32 pixel image with 128 wavebands of approximately 9 nm bandwidth over a range of 855–2036 nm (tree mode) or 1200–2400 nm (rock mode). (59) Wessman et al.,(60) conducted an experiment using AIS data of a mixed species forest in Wisconsin. They established a regression equation, based on three wavelengths, between the first-difference reflectance spectra and the lignin content of 18 stands \( (r^2 = 0.85) \). They then used a previously established inverse relationship between nitrogen mineralization (kilograms per hectare per year) and lignin to produce the first map of annual nitrogen mineralization for a forest area.

Further work using imaging spectrometers has been conducted in two major experiments, the OTTER project(45) and the National Aeronautics and Space Administration (NASA)-funded Accelerated Canopy Chemistry Program (ACCP),(61) These involved the use of the airborne visible infrared imaging spectrometer (AVIRIS) which has 224 wavebands in the range 410–2450 nm and a higher signal-to-noise ratio (SNR)
than the earlier AIS. In the OTTER project, AVIRIS data were acquired in 1990 and 1991 over six study sites along a 250-km east–west transect representing forest vegetation zones from coastal rainforest to semiarid scrub.\(^\text{40,62}\) Strong correlations between the AVIRIS first difference spectra and total nitrogen, chlorophyll and lignin measured both as canopy biochemical content (kilograms per hectare) and foliar concentration (milligrams per square centimeter). Correlations for starch were weaker for both concentration and content.

In the ACCP, AVIRIS data were acquired over a number of forest test sites in 1992 and 1993. Martin and Aber\(^\text{63}\) used data for Blackhawk Island, Wisconsin and Harvard Forest, Massachusetts, to examine spatial and temporal variation in canopy lignin and nitrogen concentrations for a total of 40 stands. They found strong correlations between first difference spectra and biochemical concentrations for both sites separately and for data combined from both sites. However, when the calibration equation derived for one site was used to predict biochemical concentrations at the other, the relationships were not significant. Errors in atmospheric correction and low SNR were suggested as possible causes for the inconsistency. Curran et al.\(^\text{64,65}\) also used AVIRIS data to estimate the biochemical composition of a slash pine canopy in Florida. They found very strong correlations between the remotely sensed data and chlorophyll, nitrogen, lignin and cellulose measured both as concentration and content.

Remote sensing is the only technique available for estimating forest biochemical properties over large areas. The research outlined above shows the great potential of the technique for providing biochemical information related to forest productivity and health and for input into process-based ecosystem models. Research to date has been limited by the availability of high spectral resolution image data with which to develop and test the techniques. The recent availability of data from the spaceborne moderate resolution imaging spectrometer (MODIS) and medium resolution imaging spectrometer (MERIS) and advances in radiative transfer modeling of leaf and canopy reflectance should ensure further progress.\(^\text{64}\)

### 4.3 Estimating Forest Stand Properties

Much of the research to develop techniques for estimating the biophysical and biochemical properties of forest canopies has been driven by the needs of forest ecologists who require the data to drive ecosystem simulation models as discussed in section 6. However, commercial forest managers may require local data on variables such as stand age, average tree height, basal area or timber volume.\(^\text{66,67}\) These variables may have no direct physical relationship with the remotely sensed signal, but they may be correlated with it through indirect relationships with LAI or canopy cover.\(^\text{68}\) A large number of studies have sought relationships between forest stand variables and a range of remotely sensed data with mixed success. Strong negative relationships have been found between R and NIR reflectance satellite sensor data and wood volume or basal area in a range of forest environments\(^\text{69–72}\) while other studies have found strong correlations with forest stand age and tree density.\(^\text{68,73,74}\) Relationships established by correlation and regression techniques depend mainly on the existence of a consistent monotonic change in reflectance as the stand develops. Such relationships may exist up to a point where the forest stand reaches full canopy cover but not thereafter.\(^\text{75}\) Furthermore, spatial variations in canopy cover or differences in terrain slope may reduce the strength of the empirical relations.\(^\text{76}\)

### 5 MICROWAVE REMOTE SENSING OF FOREST BIOPHYSICAL PROPERTIES

SAR instruments operate at microwave wavelengths between about 1 cm and 1 m and provide image data which are sensitive to the macro structure of a forest canopy. Microwave signals, in contrast to optical wavelengths, are unaffected by atmospheric conditions, including clouds, because the wavelength of the radiation is several orders of magnitude larger than the atmospheric particles.\(^\text{77,78}\) This means that SAR instruments have an all-weather day/night imaging capability, which is a major advantage for imaging the cloudy temperate regions of the Earth. The processing and analysis of SAR data are relatively complex with the magnitude of the backscattered radiation dependent on both wavelength and polarization. However, in general terms longer wavelengths penetrate deeper into the canopy, interact with the tree stems and ground and are sensitive to the total woody biomass whereas shorter wavelengths are scattered within the canopy and may be sensitive to canopy leaf area. SAR may transmit and receive radiation in either vertical (V) or horizontal (H) planes or polarizations and several studies have shown that the microwave response to forest biomass is also dependent on polarization.

Recent research on the microwave response of forest canopies has benefited from the availability of data from spaceborne instruments, in particular the C-band (3 cm) active microwave instrument (AMI) on ERS-1 and ERS-2, the L-band (23 cm) SAR on JERS-1 and more complex data from the Shuttle
Imaging Radar C (SIR-C) flown on the Space Shuttle Endeavour in 1994 (C and L band). In addition, sophisticated airborne SAR instruments such as the C-, L- and P-band (50 cm) airborne synthetic aperture radar (AirSAR) have provided an opportunity to test the application of multifrequency polarimetric data.

Many studies have found positive nonlinear relationships between microwave backscatter and forest above ground biomass, with saturation of the signal occurring at different levels depending on the wavelength measured. For example, Ranson et al. showed that SIR-C data could be used to map above ground woody biomass of Boreal forests to within 16 t ha\(^{-1}\) with sensitivity up to an upper limit of 150 t ha\(^{-1}\). Similar wavelength-dependent upper limits to biomass estimation have been found by other authors, including Imhoff, who found that the C band was sensitive to forest biomass up to 20 t ha\(^{-1}\), L band up to 40 t ha\(^{-1}\) and P band up to 200 t ha\(^{-1}\). Other studies using AirSAR data have shown that cross-polarized data are more sensitive to forest biomass than like-polarized data (Figure 2).

In addition to the work on estimating forest biomass, there have been many investigations of the application of SAR data for mapping forest areas. Unlike classification of data from optical remote sensing systems, SAR classification of forest cover types exploits differences in macro structure between stands of different species or different age or density. Other advances have been made with nonimaging radar sensors such as the use of dual-frequency ranging scatterometers to estimate forest stand structural properties.

6 REMOTE SENSING INPUTS TO FOREST ECOSYSTEM MODELS

Recent research using global climate models (GCMs) has suggested that forest ecosystems may be very sensitive to increases in atmospheric CO\(_2\) concentrations through physiological and structural responses, with important feedbacks to global climate. Climatic simulations and some recent measurements point to large temperature increases in the northern high latitudes where temperate forests are the main land cover. Intimately related to these climatic effects is the nature of the global carbon cycle. Seasonal variations in atmospheric CO\(_2\) have been related to size of the terrestrial carbon store and suggest that the northern forests represent a net “sink” for atmospheric carbon of 1–2 Gt yr\(^{-1}\) due to an increase in the length of the growing season at higher latitudes. The spatial extent of the temperate forest biome, its relationship to climate and its importance as a carbon store therefore make it important to understand its function and to model the key ecosystem processes. This is a difficult task, however, because of the complex interactions between the forest and atmosphere and the nature of the feedback mechanisms between the climate system and the biophysical, biogeochemical and structural characteristics of the forests. Detailed point measurements of these processes have been made using instrumented towers at forest test sites, but extrapolating these measurements up to regional scales (10–1000 km) requires the data on forest biophysical and biochemical properties derived from remotely sensed data using the techniques described earlier.

Forest ecosystem models describe the processes of photosynthesis and evapotranspiration which control the exchanges of energy and matter with the vegetation and they may be used to estimate the rates of cycling of carbon, water and nitrogen through the ecosystem in addition to net primary productivity (NPP). The Forest BGC model of Running and Coughlan was designed specifically to use remotely sensed input
data to determine LAI and a range of meteorological variables. At a local scale, Forest BGC was used to estimate the carbon accumulation in a Sitka spruce (*Picea sitchensis*) plantation in south Wales, UK.\(^9^9\) High spectral resolution image data from the compact airborne imaging spectrometer (CASI) were used to relate the reflectance red edge to stand LAI and leaf nitrogen content and to drive the model. Estimates of stem carbon production from the model were comparable to estimates derived from tree cores (root mean square error = 0.34 Mg Ch⁻¹ yr⁻¹). Running et al.\(^9^8\) used NDVI data from the National Oceanographic and Atmospheric Administration (NOAA) advanced very high resolution radiometer (AVHRR) to estimate LAI for a 1200-km² forested area in northwestern Montana and coupled this with daily meteorological data to estimate regional evapotranspiration and photosynthesis using Forest BGC. Estimates of aboveground net primary production and stem volume growth for the sites across the region were in the same range as those from earlier local-scale studies. Validation of the results for the 1.1-km pixel area of the AVHRR instrument was not possible, however, and the sensitivity of the model to the remotely sensed LAI estimates was highlighted as an area which required further investigation.

Liu et al.\(^1^0^0\) used a land cover classification from TM data to stratify a Boreal forest area into different forest types before estimating LAI for input into a forest productivity model. A similar approach was used by the same group\(^1^0^1\) to produce a Canada-wide NPP map using remotely sensed data, daily meteorological data and information on soil texture. All of this work shows the considerable potential for remote sensing inputs to forest ecosystem models; as techniques for estimating the model variables become more sophisticated and more accurate, and techniques for assimilating other data are developed, further advances are likely.

### 7 DEVELOPMENTS IN FOREST RESOURCE ASSESSMENT BY REMOTE SENSING

Assessment of forest resources by remote sensing depends on the existence of relationships between the
forest spectral signature and the variable of interest, e.g. canopy nitrogen concentration. Much of the work done to date has sought statistical relationships between the spectral variables and the forest variables, often with some success. A problem arises, however, when no statistical relationship can be found. Recent work has started to address this problem by developing radiative transfer models that describe the interaction of electromagnetic radiation with the leaves, branches and canopies of forests. These models can be used to simulate the reflectance of forest canopies by running them in the “forward” mode where data on the forest canopy variables are the inputs and the spectral signature is the output (Figure 4). They have also been used to estimate forest biophysical properties by applying them in the “inverse” mode where the spectral signature is the input and estimates of the forest biophysical variables are the outputs. Although this work is in the early stages of development, the approach is potentially more robust and more accurate than the statistical techniques currently used.

Studies at a regional to global scale have been stimulated by the results of work that has suggested a close link between vegetation and climate. Myneni et al. measured the change in global NDVI using AVHRR data from 1981 to 1991 and found evidence of increased vegetation activity over the period, particularly north of 45° north across the evergreen coniferous forest belt. The change in NDVI suggested an increase in the length of the active growing season in this region and was consistent with the observed increase in the amplitude of the seasonal cycle of atmospheric CO₂ concentration. Further advances in understanding the links between vegetation growth and climate are likely as the length of the satellite record increases and new spaceborne sensors for global environmental monitoring are launched.

At a local scale there have been recent developments in exploiting the spatial variation in remotely sensed images to complement techniques that use the spectral variation. A number of studies have shown that high spatial resolution data may be used to automatically determine structural variables in forest stands and to increase the accuracy of estimates of biophysical variables. The availability of high spatial resolution data from space should provide the stimulus for further developments in this area.

8 CONCLUSIONS

Forest resource assessment by remote sensing began in the first part of the twentieth century with local-scale forest mapping from aerial photography. Since that time there have been significant advances in remote sensing technology which have allowed forest resources to be assessed over much larger areas. Advances in understanding remotely sensed data have led to exciting new developments in determining the biophysical, biochemical and structural properties of forest canopies and have provided the key input data to forest ecosystem models. In addition to their role as a source of timber products, forests are increasingly being seen as an ecological resource and as a key component of the global ecosystem. The combination of new remote sensing technology and new data analysis techniques with advances in remote sensing science and ecosystem modeling have assured a critical role for remote sensing in mapping, monitoring and managing temperate forest resources.

Tropical Forest Resource Assessment by Remote Sensing

Doreen S. Boyd
Kingston University, Kingston upon Thames, UK

1 INTRODUCTION

Tropical forest regions are often impenetrable in nature, they cover vast areas and are complex environments whose exploitation has ramifications globally as well as locally. The plethora of data on forest resources, collected using traditional techniques, often lack uniformity of coverage, quality and content. The information available is scattered and diverse, compilation is difficult and synthesis all too rare.\(^\text{(2)}\) Many of the inherent difficulties of working within tropical forest environments, however, may be overcome through the use of remote sensing.

Remote sensing can be used to observe the dynamics of tropical forests at almost any level of detail.\(^\text{(3)}\) It allows the frequent measurement and monitoring of the world’s tropical forests on a continuous basis,\(^\text{(4)}\) from which accurate and informed judgments on their resources at any given time can be made. Accordingly remote sensing approaches for the collection of tropical forest resource information have progressively evolved, with the focus shifting from remotely sensed data acquired by aerial cameras to spaceborne sensors.\(^\text{(5)}\) Particular benefits of the adoption of remote sensing for the assessment of tropical forest resources are that (1) the data are spatially continuous and consistent in nature; (2) synoptic coverage is achieved with more intensive spatial sampling than the sparse point samples traditionally taken, allowing the spatial extension of ground estimates which would be impossible without extensive and costly ground surveys;\(^\text{(6)}\) (3) data are collected in a digital format with access to them and the methods for their processing becoming increasingly easy.\(^\text{(7)}\) Moreover, the digital format of remotely sensed data is conducive to computer-based analysis and integration with other data sets within a geographical information system (GIS);\(^\text{(8)}\) (4) remote sensing provides a low cost per unit area means of resources data collection and (5) the frequency of data collection is high which permits the incorporation of temporal information into an analysis,\(^\text{(9)}\) affording a long-term database for the examination of the dynamics of resource use. The latter point is also a particular advantage in view of the fact that many areas of tropical forests undergo gradual rather than dramatic change. Periods of drought, for example, have lead to the gradual degradation of large tracts of forest in several regions of southeast Asia.\(^\text{(10)}\)

Any resource information which may be inferred from the remotely sensed data acquired by spaceborne sensors will always be expressed first as a radiative property \(R\) of the forest and any background in view, which is, after atmospheric correction and to a first approximation, a function \(f\) of the location \(x\), time \(t\), wavelength \(\lambda\) and viewing geometry \(\theta\) of the given ground-resolution element:\(^\text{(11)}\) (Equation 1)

\[
R = f(x, t, \lambda, \theta) \tag{1}\]

These radiative properties are then processed and interpreted to extract resource information, of which there are three levels of detail. The first level refers to

information on the spatial extent of tropical forest cover, which can be used to assess the rate of forest dynamics; the second level comprises information on the types of forest encompassing forested areas and the third level provides information on the biophysical properties of these forests. The assessment of such tropical forest information over time puts into effect the comprehensive monitoring of tropical forest resources.

Preprocessing requirements of the remotely sensed data prior to resource information extraction is dependent primarily on the subsequent use of the data. In general, the two processes of image rectification and restoration and image enhancement are performed. Image rectification and restoration involves the processing of raw data for geometric and radiometric corrections. This enables the user of the data to locate themselves accurately in relation to the ground and utilize remotely sensed data acquired over time and space. The objective of image enhancement is to form new data from the original data in order to increase the amount of information that can be extracted. Enhancements involving multiple spectral bands of imagery (e.g., vegetation index production, principal component analyses) have been readily employed. Of most relevance to the remote sensing of tropical forest resources is the production of vegetation indices. Vegetation indices are simple mathematical expressions that combine spectral measurements in two or more spectral channels to provide nondestructive estimates of the properties of vegetation. The most popular and widely used index is the normalized difference vegetation index (NDVI) which is a two-dimensional transformation of channels acquiring radiation in visible and NIR wavelengths, \( \frac{(NIR - \text{visible})}{(NIR + \text{visible})} \). The NDVI is an indicator of instantaneous biophysical rates of vegetation and has been found to be highly correlated with vegetation properties such as above-ground biomass and leaf-area index.

There are a number of spaceborne sensors operating to provide remotely sensed data for the measurement of tropical forest resources (Table 1 provides a sample of these). The data from these sensors may also experience radiometric and atmospheric calibration and various levels of preprocessing or may be compiled to provide complete coverage of an area of interest. For instance, there are currently a number of data sets available from the data acquired by the NOAA AVHRR. One such data set is available at 1 km spatial resolution, the large area coverage (LAC). This data set is routinely collected for several continents and data-processing stations are being set up around the world for complete AVHRR “1 km” coverage. Another data set, the Global Area Coverage (GAC) sets, is displayed at a reduced spatial resolution (4 km) through the on-board resampling of the radiance recorded, thus providing data on truly continental and global scales. The Global Rain Forest Mapping (GRFM) Project has acquired contiguous SAR data sets of the earth’s major tropical forests using the JERS-1 satellite. This effort led by the Earth Observation Research Center of the National Space Development Agency of Japan (NASDA) is focused on the tropical forest regions of south and central America, central and western Africa, southeast Asia and northern Australia. Each region was observed at least once during a “single season” between September 1995 and January 1997. The final data set comprises 7500 processed SAR scenes and forms the only data set of its kind (NASDA, 1998; http://www.eors.nasda.go.jp/Sciences/Forest).

Unfortunately, there is no one spaceborne sensor currently in use that meets fully the requirements of a tropical forest resources assessment system, with the spatial resolution and frequency of coverage logistically competitive and exclusive of one another. Moreover, the radiation from which tropical forest resources are inferred are sampled at suboptimal spectral resolutions. However, with consideration given to the nature of the desired resource product, an appropriate sensor or combination of sensors may be employed.

2 TROPICAL FOREST EXTENT AND CHANGE DYNAMICS

Techniques for measuring the extent of tropical forests and their change have evolved rapidly in the 1980s and 1990s, with the development of remote sensing techniques vastly improving the capability to do so. A comprehensive evaluation of tropical forest resources requires information on how much tropical forest remains and where those areas are situated. Remote sensing is particularly well placed to provide this, particularly at the regional to global scales.

The remote sensing of the extent of tropical forests and their change dynamics falls naturally into two procedures. The first centers on the delineation of forest from nonforests and the calculation of the areal extent of forest cover. When this exercise is performed on two or more dates, an estimate of deforestation or regeneration within that time period may be made. The second procedure uses the occurrence of forest fires as an indicator of active areas of forest burning which can be used to estimate forest loss per se. Both procedures enlist a multitude of remote sensing methods, employing data from a host of sensors to perform their tasks. The optimal approach to acquiring information on tropical forest cover and their change dynamics is still under consideration.
2.1 Delineating Forest Cover from Nonforest Cover

Pioneering studies illustrated the potential of fine spatial resolution sensors\(^ {20,21}\) for the delineation of forest cover from nonforest cover, prompting the use of sensors such as those carried on the Landsat and SPOT series of satellites. These sensors have been employed to study forest area dynamics mainly at local and national scales.\(^ {22-24}\) The use of these data, particularly at regional and global scales, is, however, compromised by their expense (cost per image multiplied by number of images required to cover area of study), data load and processing requirements and the low frequency of data acquisition, compounded further by the cloud cover in tropical regions and frequent smoke from forest fires.\(^ {25}\) Furthermore, the classification of land cover requires good knowledge of the area under study, which is difficult to achieve beyond the national level.\(^ {18}\) Much consideration has been given to the use of remotely sensed data acquired by the NOAA AVHRR series of sensors. By virtue of its properties, that is its spatial resolution and temporal resolution (providing near-daily coverage), this sensor provides an invaluable data source for coarse-scale land cover studies and has been proposed as the foundation of a global monitoring system.\(^ {18,26}\) The use of SAR systems which operate in microwave wavelengths affords the certainty of cloud-free data. The ever increasing proliferation of spaceborne SAR sensors can build on the recommendation of early studies, which report them to be well suited to the mapping of forest cover.\(^ {27,28}\)

A number of approaches using remotely sensed data have been used to delineate forest cover from nonforest cover. Each approach has implicit advantages and disadvantages and are discussed in turn.

The visual interpretation of a remotely sensed image conducted by trained people with knowledge of the forested area under study has been used in a number of studies, particularly those focusing on national or subnational areas. The interpreter relies on spectral and spatial pattern recognition. The shape, size and pattern characteristics of pixels having similar spectral responses in a single channel or a combination of up to three channels may provide insight to the arrangement of forested areas and nonforested areas. Tucker et al.\(^ {29}\) inspected a NOAA-7 AVHRR image acquired on 9 July 1992 of Rondonia, Brazil and relied mainly on spectral differences between pixels. A series of linear features of higher spectral response in the SWIR channel, and to a lesser extent in the visible and NIR channels (combined within the NDVI) along highway BR-364, were detected and classified as nonforested areas. These were confirmed through field verification as forest clearings associated with a large colonization program. Other researchers have taken advantage of image texture.

Texture is evident in fine spatial resolution imagery and refers to the variance of pixel values associated with a particular object. Texture is prevalent in images of tropical forests acquired by sensors such as Landsat TM and SPOT HRV and is probably a result of canopy complexity and the relative sizes of crowns and pixels. The texture associated with a forested area will be different from that of a nonforested area and therefore can be used in the delineation between these two cover types.\(^ {30}\)

Human interpretation of images allows the large variations in feature appearance that occur with different satellite viewing angles and directional bidirectional reflectance of different surfaces to be acknowledged and accounted for. However, the approach can be time-consuming, difficult and subjective rather than operational. Furthermore, it may be wasteful of information, since it is based on an image representation of, at most, three spectral bands at any one time. With the advent of more sophisticated methods, the visual interpretation approach is more often used in the preliminary inspection of imagery or in combination with other approaches.\(^ {31}\)

The binary division of remotely sensed data into a forest or nonforest class allows the application of a radiance threshold to remotely sensed data, whereby those areas having a spectral response on either side of the threshold are allocated to a respective class.\(^ {32,33}\) The success of this approach is enhanced if images are chosen at a time when spectral contrast is maximized. SWIR and MIR radiation provides a relatively large spectral contrast (compared with that in visible and NIR wavelengths) between mature forest and other land cover.\(^ {25,34,35}\) In the separation of dense forests from degraded less homogeneous vegetation, NIR radiation appears useful.\(^ {34}\) SAR data have also been used in thresholding, whereby the use of L-band microwaves provides better discrimination than C-band.\(^ {36}\)

Full utilization of the spectral information acquired by a sensor for the delineation of forests from nonforests can be achieved using digital unsupervised or supervised classifications. The overall objective of image classification procedures is to categorize automatically all pixels of the area of study into land cover classes, in this case to represent forest and nonforest, using the pixel-by-pixel spectral pattern present.\(^ {12}\) In an unsupervised classification the image data are classified by the automatic clustering of spectrally similar pixels. These clusters are then identified by comparing the classified image to ground reference data. The unsupervised approach can be favored over the supervised classification since it does not require a demanding definition of training areas, it is objective and faster to execute.\(^ {31}\) Supervised classifications involve three main stages, the initial training stage, the classification stage and the output stage. The training stage involves the characterization of pixels of known class membership,
in this case forest and nonforest, from which class spectral “signatures” are derived. Reference data for the training stage may be derived from reliable cartographic data or via field verification. In the classification stage, these training statistics are used to allocate pixels of unknown class membership to a class in accordance with some decision rule. After the entire data set has been classified, the results are presented in the output stage, which may consist of a thematic map or tables of area statistics and the like. There are many examples of successful unsupervised and supervised classifications of forest and nonforested areas.\(^{37,38,40}\) The quality of the classification output is evaluated by comparison against some ground or other ancillary reference data from which quantitative measures of accuracy may be derived.\(^{39}\)

By studying the temporal response of remotely sensed data, that is imagery acquired over the same area at different times of year, a considerable amount of useful information can be obtained for the delineation of forests from nonforests. The general change in spectral response from areas of forest and nonforest can be characterized and utilized.\(^{41}\) However, it must be remembered that availability of imagery may be restricted by cloud cover contamination and costs. Moreover, preprocessing requirements are demanding since comparison of images requires the time-consuming task of radiometric and atmospheric correction of the remotely sensed data. Nonetheless, the attractiveness of this approach has been advocated. Conway\(^{42}\) visually inspected a multitemporal sequence of ERS-1 SAR imagery over a study area located in Papua New Guinea. The intensity of the forest pixels was seen to be more temporally stable in comparison with that of the nonforest types. This inspection revealed that savanna pixels were best discriminated from forest pixels during the dry season. Other studies have employed NOAA AVHRR NDVI and surface temperature (derived from the TIR channels) temporal variations.\(^{43}\) The temporal evolution curves of NDVI and surface temperature for a number of vegetation types of West Africa are shown in Figure 1. These curves illustrate that discriminating between the forest cover and nonforest cover is possible, particularly at certain time periods. The significance of this information is evident in Figure 2 which illustrates the enhanced separability achieved between forest and nonforest using an image acquired in the dry season (22 January and 1 February) as opposed to the wet season (17 May). The combination of remotely sensed data from multiple sensors (synergy) has been demonstrated to provide improved delineation of forests from nonforests. Synergy

![Figure 1](image_url)

**Figure 1** Temporal evolution curves of NOAA AVHRR NDVI and surface temperature for two study areas: (a) and (b) Marahue National Park and (c) and (d) Haut-Sassandra Forest, within the Guinean zone of tropical forests in West Africa. within remote sensing refers to the utilization of two or more data sets together in order to extract more information from their combination than could be extracted from the respective data sources individually.\(^{(44)}\)

The use of multisensor data allows the combination, on the one hand of spectral information from different parts of the electromagnetic spectrum, and on the other of fine and coarse spatial resolution data.

The synergy of spectral data from different sensors allows utilization of the exclusive information about the forest and nonforest that is provided by specific parts of the spectrum. Particularly attractive is the use of data acquired by optical sensors with microwave sensors. Optical sensors provide information primarily about canopy characteristics whereas microwave sensors provide information on stand attributes, such as wood biomass and geometric structure, as well as soil characteristics (e.g. humidity). Furthermore, the cloud penetrating capabilities of microwave sensors allow areas that have missing data to be included in the analyses, particularly if multitemporal methods are being employed.\(^{(45)}\)

Nezry et al.\(^{(46)}\) used LHH band SAR data acquired by the space-shuttle mounted Spaceborne Imaging Radar (SIR)-B superimposed with the three channel SPOT-1 HRV XS (high-resolution visible multispectral) data to classify the vegetation of central Sumatra using the maximum likelihood method. A visual accuracy assessment revealed the classification to be more accurate than that obtained using the SIR-B imagery alone. Correlation coefficients between the three SPOT channels and the SIR-B channel of part of the study area revealed the nature of the information provided by these images to be globally very different.

The benefits of using multispatial sensor data has been demonstrated by many researchers.\(^{(47-49)}\) The ability of a particular remote sensor to undertake the task of mapping forest and nonforests is dependent upon the sizes of the deforested areas under study, the spatial arrangement of these and the spectral contrast between the deforested areas and the original forest.\(^{(50)}\) For example, large discrete clearances with distinct geometric boundaries, such as cattle ranches in eastern Amazonia will often be detected at the 1.1 km spatial resolution expressed in the AVHRR sensor data, even in cases where spectral contrast is minimal.\(^{(50,51)}\) However, close to the margins of clearance and where a complex arrangement of forest and nonforest areas or small clearances exist (e.g. in Rondonia, Brazil), the estimation of the true spatial extent of forest clearance would require the use of data collected at a finer spatial resolution. However, the choice of sensor in a particular study may be determined by practicalities such as availability of funds, processing capabilities and time constraints, rather than theoretical knowledge. Coarse spatial resolution imagery is often used in large scale studies, which produce estimates of nonforest/forest which are inaccurate locally because of spatial aggregation errors, but acceptable over the entire population.\(^{(18)}\) Whereas fine spatial resolution imagery used in the more local scale studies produces accurate estimates for that area, extrapolations over other areas where the imagery is unavailable may be inaccurate because of spatial variability.

The problems associated with using coarse spatial resolution data have been particularly well documented.\(^{(4,17)}\) Generally, as the spatial resolution of an image decreases, so a greater proportion of pixels will have a partial forest
cover and the accuracy of a forest/nonforest classification will decrease. Pixels comprising imagery acquired by current coarse spatial resolution sensors typically represent a ground area of 1.21 km² and so the vast majority of pixels will contain two or more land cover classes. These mixed pixels cannot be accommodated or appropriately represented in the methods described above, where each pixel may only be associated with one class, in this case forest or nonforest, leading to a classification error. Skole and Tucker suggested that NOAA AVHRR data overestimated the deforested area in the Legal Amazon by as much as 50% in comparison to estimates derived using Landsat TM data. Cross et al. also observed that at least 66% of the AVHRR ground pixel needed to be forested for inclusion in a forested class within the classified image. As a consequence the extent of forest cover may be underestimated which could result in an overestimation of deforestation rate.

It is possible to compensate for misclassification bias by focusing on the validation and correction of regional estimates of deforestation, although the spatial distribution of deforestation will still be erroneous. Forest/nonforest classifications based on coarse spatial resolution data are compared with classifications of a sample of coregistered finer spatial resolution data. Corrections may take the form of a simple regression between the classification at the two spatial resolutions by obtaining the relationship between the two sets of data as an indication of the extent to which the coarse spatial resolution data represent the areally integrated spectral response of the ground surface at the pixel resolution of the sensors. Others have stratified the coarse resolution classification according to the degree of forest fragmentation across the area of study prior to regression formulation. Misclassifications occurring as a result of image quality, atmospheric variations, topographic and bidirectional reflectance effects, a particular problem with studies using image mosaics, may also be addressed using this approach.

Another approach aimed at improving the classification accuracy of coarse spatial resolution imagery is to unmix the land cover composition of each pixel. Thus rather than derive a conventional “hard” image classification whereby each pixel is classified as either forest or nonforest, estimates of the class composition of each pixel may be derived. These may be used to derive fraction images, which display the proportional coverage of a particular class (in this case either forest or nonforest) in each pixel. Although such techniques fail to provide information on the exact location of the subpixel compositions, the accuracy of forest cover estimation is often improved. Techniques currently receiving attention are mixture modeling, artificial neural networks (ANNs) and subpixel calibration.

Linear mixture modeling is one approach used to produce the class composition of pixels, as a precursor to the production of fraction images. This approach assumes that the spectral response recorded for a pixel is simply an additive function of the spectral response of each class weighted by its proportional coverage of the area represented by the pixel. The use of this approach in a forest/nonforest classification requires knowledge of image end-members, which in this case would be the spectral response in each channel utilized from a pure forested pixel and a pure nonforest pixel. This information is used within the linear mixture model and for each pixel in the image the proportion of each class computed. Cross et al. implemented a linear-mixture model with channels 1 to 4 of AVHRR to derive forest cover estimates of Rondonia, Brazil and Ghana. The model produced image outputs in which the pixel intensities indicated the proportion of forest cover per square kilometer. Comparisons were drawn with a Landsat TM and an AVHRR classification performed using traditional methods, and improvements in the accuracy of forest cover extent noted. In general, mixture models applied to coarse resolution data enhanced the classification of forest/nonforest where discrete areas of forest are cleared but the models are less successful where a complex type of forest clearance exists (e.g. shifting cultivation) and in areas where only slight variations in the spectral response of forest canopies indicate forest disturbance. Mixing from vegetated targets is often distinctly nonlinear in optical wavelengths owing to factors such as multiple scattering and in thermal wavelengths owing to Planck’s function. This restricts the available data to be used in the model, though success using MIR radiation corrected for thermal emission has been noted. Obtaining the class spectral response or end-member spectra to represent the remotely sensed response that would be observed if the pixel represented a homogeneous region comprised of either forest or nonforest, is a further problem. As the vast majority of pixels in an image are likely to be mixed, it is therefore unlikely that the end-member spectra could be derived directly from the imagery. Moreover, nonforest classes may need to be represented by a variety of spectra since pastures of different ages are spectrally distinct, as are plantations, roads and so on. It is possible to use library spectra or, as Adams et al. demonstrated, laboratory or field spectra of materials contributing to the reflectance of each pixel over the study area. Here, reflectance spectra from 400–1000 nm of primary forest canopy were measured from towers, and samples of soil and vegetation were collected in the field and measured in the laboratory over the wavelength range 400–2500 nm. In this instance, these spectra were used in a spectral mixture analysis method applied to multitemporal Landsat TM imagery.
An ANN approach has also been used as a method of deriving the class composition of pixels. ANNs are a form of artificial intelligence that can be trained to learn by example and therefore may be used to recognize the forest/nonforest composition of pixels if trained using appropriate data. Foody et al.\textsuperscript{57} used an ANN to map tropical forest cover over a 3000 km\textsuperscript{2} region of the Mato Grosso, Brazil. The ANN was trained using coarse spatial resolution NOAA AVHRR data acquired in visible, NIR and MIR channels of which the land cover composition (forest, nonforest and water) had been determined from a coregistered Landsat TM image. The training data comprised data with a range of class compositions allowing the network to recognize the relationship between spectral response and forest cover, nonforest cover and water cover, respectively. Once trained, the ANN was used to allocate a class composition of forest, nonforest and water to the remaining pixels of the AVHRR image using their spectral response. The success of this method can be seen visually in Figure 3, whereby the fraction images produced via the ANN provides a far more realistic representation of the forest cover at the study site. Use of an ANN is attractive since it is able to use mixed pixels in the training stage and it does not assume linear mixing of the classes comprising the pixel’s spectral response.

In the ANN approach outlined above, the network is essentially being employed as a regression model whereby the training data is used to determine the relationship between percentage of forest cover and spectral response. Indeed this approach can also be adopted using standard empirical regression modeling. Here a relationship between percentage forest cover and spectral response is determined through classification of finer spatial resolution imagery into forest and nonforest cover. The class proportion of a pixel in the coarse spatial resolution imagery is determined by the percentage of fine spatial resolution pixels classified as forests comprising the same area as the coarse spatial resolution pixel. This is conducted for a sample of coarse spatial resolution pixels and the resultant empirical relationship is applied to the remainder of the imagery and the percentage forest cover of the whole study area determined.\textsuperscript{64}

The success in using remotely sensed data for the assessment of tropical forest extent and change dynamics has led to the implementation of major programs that are using remotely sensed data to map and monitor tropical forests, including the following.

2.1.1 United Nations Food and Agricultural Organization

The United Nations Food and Agricultural Organization (FAO) has undertaken periodic assessments of the

![Figure 3](image-url) Forest cover delineated from nonforest cover using a supervised classification on (a) the NOAA AVHRR image (light tone area is cloud) and (b) the Landsat TM image. The forested area is readily identifiable on Landsat TM image (gray grainy tone) compared with the NOAA AVHRR image. (c) displays the fraction image illustrating forest cover derived by unmixing the AVHRR pixels with an ANN. The proportion of forest cover in a pixel is related to image tone (black = 100% forest cover and white = 0% forest cover). Note the improved delineation of forest cover from nonforest cover achieved on the fraction image over the hard classification of the NOAA AVHRR image. (Reproduced by kind permission of Kluwer Academic from Foody et al., \textit{Plant Ecology}, 1997,\textsuperscript{57})
earth’s forest resources, including those of tropical regions, since 1946. In 1990 the Global Forest Resources Assessment was launched which had a remit to provide comprehensive information on the current state of global forests and recent changes including areal extent, growing stock, management and conservation and environmental functions of the forests. This assessment realized the contribution that remote sensing could make to the collection of such information. A remote sensing survey (FAO-RS) was included in the assessment and aimed to produce the resources information needed for the tropical forest zone. The survey employed 117 Landsat TM images, covering 10% of potential tropical forest land. Of these images, 47 covered African locations, 30 covered Asian and 40 Latin American. At each location satellite images of the best quality and appropriate season, separated by an approximate 10-year interval, were selected for interpretation. Local teams having good knowledge of the locations interpreted the multidate images visually to identify nine cover classes, four of which were “forest classes”: closed forest (canopy cover >40%); open forest (canopy cover 10–40%); long fallow (forest affected by shifting cultivation) and fragmented forests (mosaic of forest and nonforest). Used within a GIS along with geo-referenced data such as ecological zones and population density, these land cover classes indicated tropical forest-cover change at global scales for the decade 1980 through 1990 and then the current (1990) state of tropical forest cover.

2.1.2 Tropical Ecosystem Environment Observations by Satellites
The Tropical Ecosystem Environment Observations by Satellites (TREES) project of the European Commission’s Joint Research Center (JRC) initiated in 1990 aimed to develop global forest cover assessment methods for the humid tropics and produced a set of tropical forest-cover maps and forest area statistics by country. The project makes use of NOAA AVHRR and ERS-1 SAR data, which are mostly selected in the dry season in order to obtain better contrast between forests and other more seasonal cover types. When seasonal forest is present, the use of a few dates at different stages of the dry season allows the distinction to be made between the evergreen and deciduous formations. Classification by unsupervised methods are applied to quality cloud-free parts of single-date images. Clusters derived are interpreted and labeled. Labeling is based on available field knowledge, ancillary information (existing national forest maps) and a visual analysis of spatial distribution pattern. Single date classifications are assembled into a simple mosaic map and overlapping classifications are chosen on the basis of a “reliability” indicator. The final product is a map of forest distribution at 1.1 km spatial resolution. Three main classes are distinguished relating to the proportion of forest cover in the AVHRR pixels: (1) dense humid forest (>70% forest cover in each pixel); (2) fragmented or secondary forests (10–70% cover); (3) nonforest (<10% cover) including savanna, agricultural land and urban areas. Maps are corrected using finer spatial resolution Landsat TM imagery.

2.1.3 The Landsat Pathfinder Tropical Forest Inventory Project
This project was conducted by the National Aeronautics and Space Administration (NASA). It aimed to provide maps of the rates of deforestation in the tropics through the intensive use of high-spatial-resolution satellite data from three epochs; early 1970s, mid-1980s and mid-1990s. Coverage was of three regions containing 75% of the world’s tropical forests and the source of information was wall-to-wall coverage of high-spatial-resolution data (Landsat MSS (Multispectral Scanning System) and TM). Data processing combines automated classification and visual image interpretation. Results are manually edited and merged into a seamless database. The three epochs’ interpretation are fed into a GIS and deforestation rates are computed.

2.1.4 The Global Resource Information Database Approach
This is the environmental data support component of the Global Environment Monitoring System (GEMS) at the United Nations Environment Programme (UNEP). The mission of Global Resource Information Database (GRID) is to provide a globally comprehensive data base of current tropical forest cover, derived from the analysis of NOAA AVHRR imagery. The proposal is to update the map at least every 3–5 years. The analysis of the imagery and the construction of the database is being undertaken in collaboration, both formally and informally, with 12 research/educational organizations in Brazil, Europe and the USA.

2.1.5 The Large-scale Biosphere Atmosphere Experiment
The Large-scale Biosphere Atmosphere (LBA) in Amazonia is an international research initiative led by Brazil. The land use and land cover change component of this experiment is interested in the spatial pattern of forest cover and its change. Current remote-sensing algorithms and techniques on remotely sensed data acquired by a broad constellation of satellite sensors will be used to provide such information. Further development of algorithms to process microwave sensor images will also be conducted (LBA; http://daacl.esd.ornl.gov/lba_cptec).
2.2 Fire Occurrence

Remotely sensed data may be used to provide information on biomass burning which can indicate the magnitude and temporal dynamics of forest cover change through deforestation by burning events. The occurrence of biomass burning is indicated by the presence of active fires, burn scars and smoke plumes, all of which are detectable via remote sensing. There are many examples of the use of remote sensing to observe smoke plumes over tropical forests (e.g. Hellfert and Lulla). However, in terms of measuring changes in forest cover it is important to be able to detect when and where and how much of an area of forest has been burnt. These variables are best estimated through active fire detection which provides the temporal and locational information and burn area estimation which allows the quantification of change in forest cover through burning. Inferences of fire activity type may also be made from such information, which in turn is indicative of the mechanisms promoting forest change. For example, regular patterns of fire activity are indicative of organized clearance, linear fire patterns may suggest the movement of the fire front or road construction and multitemporal analysis detecting small, scattered and repeated fire occurrences in one particular area may indicate the rotation cycles for shifting cultivation.

Theoretically, active fires may be detected by any remote sensor carrying an MIR or TIR channel. Active fires emit radiation vigorously in these wavelengths, providing a signal that appears widely divergent from its surroundings. The peak spectral emission associated with forest fires varies from between 8–12 µm for a cool forest fire (at 500 K), 2.9 µm for a forest fire (at 1000 K) to 1.6 µm for a maximum heat fire (1800 K), thus indicating that at these wavelengths the best contrast between a fire pixel and a nonfire pixel will be obtained. Detectors using wavelengths between 1.5 and 3.0 µm, i.e. those carried on the Landsat TM sensor, face problems of solar contamination, for example from sunglint from cloud tops. Consequently, it has been the AVHRR sensor, and more recently the ERS-2 ATSR sensor, which measure radiation at 3.53 µm, that has been used for detecting active deforestation fires (e.g. Malingreau et al., Matson and Holben, Pereira and Setzer, Perrin and Milington, Wooster et al.). The general approach is to set a threshold in the 3.53 µm channel with additional thresholds set in other channels to avoid confusion with high-reflective areas. Because of changes in fire size and background temperature, the setting of these thresholds is best done by ecological regions, which can be aided by the use of a contextual classification approach. The temporal resolution of the NOAA AVHRR satellite sensor also makes it an attractive proposition for measuring active fires and its daily revisit cycle increases the likelihood of fires in action being recorded. There are problems, however, with using AVHRR data. The 1.1 km spatial resolution and threshold temperature leads to the saturation of the pixel by small intense fires, medium to large fires of moderate intensity and by many sorts of fires if the background temperature is sufficiently high; this may lead to an imprecise location of burning activity within the ground pixel and little indication of the impact of fire on the forest environment. Small fires may be missed which also leads to incorrect estimation of remaining forest cover. Kaufman et al. estimated that flaming fires with temperatures greater than 800 K can be detected on AVHRR imagery if they occupy an area greater than 1/10000 of the pixel, while smoldering fires with temperatures above 500 K need to occupy more than 1/1000 of the pixel surface.

Burn areas provide a spectrally distinct response from the surrounding vegetation, which can be measured using remote sensing. Reflectance in the visible part of the electromagnetic spectrum is lower than that of the forest owing to the low albedo of burn scars, and NIR reflectance falls owing to the loss of photosynthetically active material in green vegetation. SWIR reflectance of fire scars is also much lower than that of the surroundings and this part of the spectrum has been used successfully for the purpose of fire scar detection in a number of studies. This radiation is currently measured by sensors such as Landsat TM and ERS ATSR-2. MIR radiation may also be used. Here the radiation acquired at MIR wavelengths is corrected for thermal emission to leave the reflected MIR, which behaves in a similar way to SWIR reflectance, its spectral neighbor.

The success of spatially delimiting burn scars as a prerequisite to estimating change in forest cover by fire events is highly dependent on the spatial resolution of the sensor used. The spatial resolution of fine resolution sensors (between 20 and 80 m) is generally sufficient to capture the spatial pattern of burn scars. However, at coarser spatial resolutions the burn scars are unlikely to be satisfactorily detected. There is the additional consideration, however, that the spectral distinctness of burn scars will diminish over time, with prompt vegetation growth and removal of the ash layer by wind. This has led to the suggestion that a multisensor approach should be adopted in which regional burnt area estimates from coarse spatial resolution data are calibrated on the basis of a sample of fine spatial resolution estimates of burnt areas.

3 TROPICAL FOREST TYPES

The forest cover delineated from nonforest cover during the first level of resource information extraction will
comprise a number of different forest types. Remotely sensed data have been used to enhance resource detail and to provide a resource assessment which relies on the knowledge of forest type. Such information, based on, for example, regeneration age, structural composition and phenological characteristics of tropical forests, is important for the assessment of resource quantity. Different forest types lend themselves to different economic uses, e.g. fuelwood versus construction timber, as well as being of a differing conservational value. The accurate measurement of forest regeneration age is also pertinent for the development of regional and global carbon budgets and the provision of information on tropical forest recovery after loss. Furthermore, since forest age may be used to infer biophysical properties such as biomass and basal area, as well as other variables such as canopy structure, roughness and species composition, its measurement is important for tropical forest resource quality assessment.

Studies exploring the remotely sensed response from tropical forests of different ages have demonstrated the capabilities of remote sensing to derive regeneration age class maps of tropical forests, at least up to the point where the primary and secondary forest spectral responses “blend”. Age class maps of tropical forests via remote sensing have been derived using one of three approaches. One has utilized the resolved relationships between remotely sensed response and age. Mausel et al., McMorrow, Steininger and Boyd et al. have all shown that the combined effect of interrelated factors such as pigment absorption, canopy water content absorption, multiple scattering within the canopy, shadows within the canopy, canopy transpiration and understorey reflectance will determine the radiation between visible and TIR wavelengths observed from the regenerating forest canopy. The influence of each of these factors will change in importance as the forest canopy ages, increasing in structural and geometrical complexity and developing a multilayered canopy. Table 2 reviews the factors determining the spectral response from regenerating tropical forests of different ages.

On the basis of such information outlined in Table 2 and preliminary analyses, Lucas et al. formulated a method for mapping of four stages of forest regeneration across the Legal Amazon using NOAA AVHRR imagery. The spectral response of each pixel in the visible, NIR and MIR channels was examined and a regeneration stage allocated on the basis of the following criteria. Stage one of regeneration was assigned to those pixels having a MIR response higher than the mean MIR response associated with mature forests. Stages II and III of regeneration were allocated to those pixels having a lower MIR response than the mean for mature forests and a maximum NIR response. The division between the two stages was based on the average visible response; pixels for which the visible response was less than and greater than the average were categorized as stage II and stage III, respectively. Stage IV was assigned to pixels having a NIR response below the mean for proximal mature forests. Accuracy assessment of the derived age class map was conducted using coregistered Landsat TM imagery at a number of sites across the Legal Amazon as reference data. The confusion matrices constructed confirmed a relatively high degree of correspondence for all sites.

Another approach to deriving age class maps has been to classify remotely sensed images of regenerating tropical forests into age classes via a supervised classification. Foody et al. adopted the maximum likelihood method

to classify a Landsat TM image of an area near Manaus, Brazil into six regenerating forest age classes and achieved a high level of class separability. Of the classification errors observed, most were found to be associated with the youngest forest age classes. At the study site, two main successional pathways during regeneration were followed and spectral differences between areas of forest of the same age but on different pathways were most apparent with the younger forest. Splitting the regenerating forests by successional pathway was found to increase classification, with an accuracy of over 90% obtained for the resultant 11 class classifications.

The last approach has been to use a time series of coregistered, multispectral images (usually Landsat TM, SPOT HRV and/or Landsat MSS data). The example of Lucas et al. can be used to illustrate the approach. The forests comprising an area north of Manaus, Brazil were aged using subset and georegistered Landsat TM imagery acquired in 1985, 1988, 1989 and 1991. By using statistics from over 60 training sites representing known land cover, and applying a minimum distance classification to the red, NIR and SWIR channels to each of the Landsat TM subsets, the broad categories of primary forest, regenerating forest and pasture were classified for each date. A majority filter was then applied to each classified image to ensure that isolated pixels were reallocated to the surrounding class. Changes in land cover at each pixel location over this six-year period were then documented to provide information on the approximate age of regenerating forests. A model of changes in land cover at Manaus, based on the multitemporal analysis is shown in Figure 4. The seven categories of land cover (five categories of regenerating forests, plus pasture and primary forest) were mapped using a GIS to produce an age class map of the forests at the study site. Ideally, the multitemporal images are acquired yearly to map regenerating forest age accurately. The image sequences, however, often have gaps due to the difficulties of obtaining cloud-free scenes, and costs and temporal discontinuities between satellite sensors. It must be remembered that this missed information could introduce unknown errors into the mapping of forest age.

A number of studies have also separated forest types defined on the basis of structural and bioclimatic attributes based largely on the degree of the forests’ canopy closure, see Table 3 for examples. Roy et al. and Saxena et al. have explored the forest types to be identified using remotely sensed data by both visual and supervised classification techniques. An analysis of the cost effectiveness of these techniques revealed the latter to be a more economical proposition. However, consideration must be given to the availability of funds, facilities and accuracy of resource information required. Other studies have concentrated on purely digital classification techniques with refinements to improve the accuracy of classifications. For example, a stratified approach was adopted by Sudhaker et al. Here forest vegetation was masked from plantations/social forest areas and classifications conducted in isolation and then composited. Classification accuracy also could be increased through the use of contextual and ancillary information, such as historical land-use information, site characteristics (i.e. topography) and geobotanical relationships (e.g. Paradella et al. Tuomisto et al. and Brondizio et al.).

The ability to map forest types using remotely sensed data could also be enhanced using interannual multitemporal data. An interannual multitemporal data set offers the potential for any temporal alteration in the spectral response from different forest types as a result of phenological change (e.g. leaf shedding, canopy greenness and senescence) to be exploited within a classification procedure. Forest types such as dense evergreen, dense seasonal and tropical deciduous have been distinguished and classified (e.g. Achard and Esteguil). At the continental and global scales the temporal variation in NOAA AVHRR NDVI has been used to map a range of vegetation types including a number in the tropical forest biome.

The heterogeneity of the tropical forest cover types and the highly complex spectral response from them account for the limited number of forest types currently identifiable by remote sensing. An improvement in spatial, spectral and radiometric resolution of remote sensors will

enhance the potential detail to be exploited. However, it must be recognized that while the total information content of remotely sensed data is determined by such prefixed sensor attributes, thematic details gained from the data depend on the interpretation techniques used for information extraction.\(^{(100)}\)

### 4 TROPICAL FOREST PROPERTIES

The measurement of tropical forest biophysical properties (e.g. leaf and wood biomass) provides an indication of resource quality, as well as resource management strategy information. In regions of southeast Asia and Africa, shifting cultivation and selective logging have resulted in structural alteration of the forest rather than wholesale clearance (Green and Sussman;\(^{24}\) Gilruth et al.\(^{109}\)) and these would be best detected through biophysical property estimation. Plantation development, site productivity and the process of natural forest regeneration after deforestation, for example, can also be inferred from biophysical properties.

Two basic approaches can be employed to relate remotely sensed data to biophysical variables. In physical modeling, the canopy radiative transfer processes are simulated mathematically with valuable insights into the fundamental factors driving the relationships between remotely sensed data and vegetation biophysical properties gained.\(^{(110)}\) However, their use for tropical forest resource assessment is presently hindered by factors such as the heterogeneity of the canopy, the dynamic characteristics of the canopy optical properties and external effects, such as atmospheric path radiance and absorption. An alternative and more operational approach is empirical modeling, whereby the quantitative relationship between remotely sensed data and various derivatives (e.g. vegetation indices) and ground-based biophysical property data is calibrated by interrelating known points of coincident observation of the two. Often statistical regression procedures are used. The use of radiometrically and atmospherically calibrated remotely sensed data to develop an empirical model affords its application at other spatial and temporal resolutions.

A fundamental problem often faced by researchers studying tropical forests is the lack of appropriate ground data which may be brought together with the remotely sensed data.\(^{(111)}\) This may account for the limited number of studies that have been conducted which focus on the estimation of biophysical properties of tropical forests using remotely sensed data. For those few studies that have actual biophysical data, initial attention has been placed on the use of remotely sensed radiation acquired in the visible and NIR wavelengths. In visible wavelengths, absorption by leaf pigments is large and therefore there is little reflection, while in NIR wavelengths leaf scattering is large and, therefore, reflection from the canopy is also large. Shadow decreases canopy reflectance in both visible and NIR wavelengths. As a consequence, leaf biomass would be expected to exhibit a negative relationship with visible radiation and either no or a positive relationship with NIR radiation.\(^{(111)}\) Improved relationship strengths are obtained when the visible and NIR radiation are combined in the NDVI, which has been shown to be directly related to the leaf area index of temperate forests,\(^{(112)}\) as well as a number of other vegetation types. Generally, however, researchers have reported weak relationships between the NDVI and a range of tropical forest biophysical properties, including Net Primary Productivity (NPP),\(^{(113)}\) stand structure (e.g. height, diameter of main stem) and biomass,\(^{(114)}\) and tree density and basal area.\(^{(115)}\) This weak relationship may be a function of a number of factors.\(^{(116)}\) First, the asymptotic relationship, with the sensitivity of the NDVI to biophysical properties seen to decline with large amounts of vegetation. Second, there is attenuation by the large atmospheric water and aerosol load above tropical forests. Third, low reflectance in the red and NIR wavelengths is observed from tropical forest canopies and fourth is the ecological and physical complexity of tropical forest environments. Subsequent studies have therefore concentrated on the validity of using remotely sensed data acquired in other parts of the electromagnetic spectrum for the estimation of tropical forest biophysical properties, namely, the infrared and microwave wavelengths.

The suitability of using MIR radiation for the estimation of tropical forest biophysical properties has been advocated. MIR radiation acquired by the NOAA AVHRR sensor, either alone or within vegetation indices, provides stronger relationships with tropical forest biophysical properties than visible and NIR radiation and derivatives of these.\(^{(117)}\) Moreover, within tropical environments, MIR radiation offers favorable atmospheric penetration capabilities. It is able to penetrate to a greater depth through anthropogenic or organic smoke particles than visible or NIR radiation.\(^{(118)}\) Contemporary thinking assigns the interaction between the forests and MIR radiation to a number of interrelated factors, principally the water content, surface temperature and structure and roughness of the canopy.

An increase in forest amount, represented by biophysical properties such as biomass and tree density, will lead to a decrease in the MIR radiation from the forest, resulting in an inverse relationship between the two variables.\(^{(116)}\) It has been suggested, however, that the use of MIR radiation at and beyond the regional scale may be unreliable. MIR radiation is composed of a mixture of reflected and emitted radiation and, at these scales, the emitted component may be more sensitive to external...
confounding variables than to the intrinsic properties of the earth’s surface. Emitted radiation, though related to forest canopy properties, may also be subject to varying soil moisture conditions, atmospheric conditions such as wind speed and air vapor conductance, as well as to site specific factors such as topography and aspect. Indeed, it is factors such as these that have been related more strongly to tropical forest canopy thermal response than to biophysical properties such as basal area and tree density.\(^{(119)}\) It may be preferable, therefore, to correct for thermal emission and use only the reflected component of the MIR radiation.\(^{(118)}\)

The reflected component of MIR radiation from a vegetation canopy is hypothesized to be principally a function of the water content of the canopy. An increase in vegetation amount will be accompanied by an increase in the amount of liquid water in the canopy, absorbing the incident radiant component of MIR radiation.\(^{(118)}\) Canopy structure, generally becoming more complex as vegetation amount increases, is also believed to be an important factor determining the reflected component of MIR radiation from a vegetation canopy. The vertical structure of the canopy has an effect on radiation absorption, by trapping incoming photons thereby producing shadows which will decrease the intensity of the reflected component of MIR radiation. So although two vegetation types may have the same leaf reflectance in the MIR spectral region, their overall reflectance will be a function of the canopy structure which may differ between the two vegetation types.\(^{(118)}\)

An exploratory study by Boyd et al.\(^{(120)}\) has revealed that correcting MIR radiation for thermal emission, to derive MIR reflectance, increases the strength of the relationship between radiation acquired in MIR wavelengths and total forest biomass of West African tropical forests. The use of MIR reflectance, either alone or within the vegetation index VI3 ((NIR − MIR reflectance)/(NIR + MIR reflectance)), provided the strongest relationship with total forest biomass. This suggests that MIR reflectance may be more sensitive to changes in forest properties than the reflectance in visible and NIR wavelengths and should be used to estimate the biomass of tropical forests.

The use of SAR remote sensing to estimate biophysical properties of tropical forests has also shown promise. It has been shown both experimentally and by theoretical modeling that the penetration of microwaves into the forest is dependent primarily upon wavelength, with a few basic categories evident. Short-wavelength (e.g. X-band \(\approx 3\) cm) microwaves interact with the surface of the canopy promoting scattering on the leaves, twigs or branches; medium-wavelength (e.g. C-band \(\approx 6\) cm) microwaves interact with the volume of the canopy/trunk volume and longer-wavelength (e.g. L-band \(\approx 22\) cm) microwaves penetrate the canopy, interacting with the ground/trunk.\(^{(111,121)}\) The depth of microwave penetration is further dependent on the angle of incidence of the sensor and canopy openness\(^{(122,123)}\) and moreover on the polarization of the microwave.\(^{(124)}\) Many SARs can both transmit and receive microwaves at two polarizations and this enhances the information provided, particularly on surface roughness and geometric regularities in the forest stand.\(^{(125)}\) Through each of these interaction types, specific biophysical properties, most commonly above-ground biomass and canopy roughness, of forests may be estimated, at least up to certain thresholds. The values reported for broad-leaved evergreen forests are 20 t (tonnes) ha\(^{-1}\) for C-band and 40 t ha\(^{-1}\) for L-band under similar conditions,\(^{(126)}\) though the use of cross-polarization microwaves and differing viewing geometries may extend that.

The suitability of SAR for tropical forest studies is determined by this saturation level, which is well below the biomass attained for mature tropical forests. Research has revealed that L-band microwaves can be used to discriminate between different levels of regenerating forest biomass (up to approximately 20 years old, 60 t ha\(^{-1}\)) and that cross-polarized backscatter is more sensitive to changes in biomass density than monopolarized backscatter. The use of C-band SAR imagery is limited to differentiating between very-low-biomass or clear-cut areas and those with some vegetation when it is dry.\(^{(127–129)}\) Improvements in the strength of the relationship between microwave data and biomass have been attained using backscatter ratios (e.g. LHV/LHH) and, moreover, by stratifying the biomass data by forest type.\(^{(130)}\) SAR data could also be suitable for estimating biophysical properties of plantation forests. Rosenqvist\(^{(121)}\) has obtained strong relationships between LHH backscatter measured by the JERS-1 SAR sensor and the height of deciduous rubber trees, and furthermore between the CVV backscatter measured by the ERS-1 AMI (Active Microwave Instrumentation) sensor and LHH backscatter measured by JERS-1 SAR and the leaf area index of oil palm stands.

Once an empirical model has been developed between remotely sensed data and a tropical forest biophysical property, that model may be extrapolated across a larger desired area with the use of radiometrically and atmospherically corrected remotely sensed data to provide a map delimiting forests of classes of biophysical properties. This has been conducted for southern Cameroon\(^{(131)}\) where a map of the carbon content of the forest was produced on the basis of basal area classes. Initial image processing used an unsupervised classification of NOAA AVHRR imagery in channels 1, 2 and 3, guided by field experience and available baseline data, to delineate the regenerating
Forests from mature forests. A significant negative logarithmic regression model derived between NOAA AVHRR channel 3 radiance and the biophysical property of basal area of tropical forests measured during a field campaign (Figure 5) was then applied to imagery of the area. From this exercise a map depicting the spatial extent of four classes of stages of regenerating forests (equating with four ranges of basal area estimated by the regression model), mature forest and nonforest was produced.

5 FUTURE CAPABILITIES

As tropical forest resources face increasing pressure so the need to acquire more accurate and timely information about their current state increases. This task will be much aided by the planned launch of new spaceborne sensors, such as Earth Observing System (EOS) AM-1 MODIS (Moderate Resolution Imaging Spectrometer), Landsat ETM (Enhanced Thematic Mapper), SPOT Vegetation, SPOT-Radar SAR and Polar Orbiting Environmental Mission (POEM) Envisat Advanced Along Track Scanning Radiometer (AATSR), which will allow the user to choose a sensor that will acquire the remotely sensed data that is best suited for the tropical forest resource information required. Through advances in technology, future sensors will have improved spectral, spatial, radiometric and temporal properties over current sensors. Moreover, more sensors will have multiple view angle capabilities. Access to remotely sensed data will also increase, with a multitude of data products which have undergone different levels of processing abounding. Different data products will enable users to choose products available at a particular processing level, enabling them to work at coarse spatial resolutions to study global resources or at finely detailed resolutions allowing the study of resources in targeted regions. With the launch of such spaceborne sensors remote sensing will continue to be a crucial tool in the assessment of tropical forest resources.

ABBREVIATIONS AND ACRONYMS

AATSR  Advanced Along Track Scanning Radiometer
AMI  Active Microwave Instrumentation
ANN  Artificial Neural Network
AVHRR  Advanced Very High-resolution Radiometer
EOS  Earth Observing System
ERS  European Remote Sensing Satellite
ETM  Enhanced Thematic Mapper
FAO  United Nations Food and Agricultural Organization
GAC  Global Area Coverage
GEMS  Global Environment Monitoring System
GIS  Geographical Information System
GRFM  Global Rain Forest Mapping Project
GRID  Global Resource Information Database
HRV  High-resolution Visible
HRV XS  High-resolution Visible Multispectral
IRS  Indian Remote Sensing Satellite
JERS  Japanese Earth Resources Satellite
JRC  Joint Research Center
LAC  Large Area Coverage
LBA  Large-scale Biosphere Atmosphere
MIR  Middle-infrared
MODIS  Moderate Resolution Imaging Spectrometer
MOMS  Modular Optoelectronic Multispectral Scanner
MSS  Multispectral Scanning System
NASA  National Aeronautics and Space Administration
NASDA  National Space Development Agency of Japan
NDVI  Normalized Difference Vegetation Index
NIR  Near-infrared
NOAA  National Oceanic and Atmospheric Administration
NPP  Net Primary Productivity
TROPICAL FOREST RESOURCE ASSESSMENT BY REMOTE SENSING

POEM Polar Orbiting Environmental Mission
SAR Synthetic Aperture Radar
SIR Spaceborne Imaging Radar
SPOT System Probatoire d’Observation de La Terre
SWIR Shortwave-infrared

Steel and Related Materials: Introduction*

Thomas R. Dulski
Carpenter Technology Corporation, Reading, USA

Metallurgy and chemistry have been intimately linked since long before either qualified as a modern science. The alchemist’s pursuit of a Philosopher’s Stone to transmute base metals into gold might be regarded as the origin of the synthetic phase of this symbiotic relationship. However, the analytical phase is much more ancient. Three thousand years ago fire assay techniques were being used to verify the purity of precious metals. These were, by any assessment, analytical procedures.

It is difficult from a modern perspective to appreciate fully how important the analysis of metals was to the emerging theory and practice of chemical science in the 18th and 19th centuries. Early texts such as Metallurgical Chemistry (1) (published in 1776 in English translation from the original German) demonstrate that even nascent, erroneous ideas (phlogiston theory, for example) were already being tested in practical application to commerce in ores and metals.

It could be argued that the Industrial Revolution was a revolution driven by metal production. The Bessemer process in 1856, the first open hearths in 1888, and the first electric arc furnaces in 1899 represent an upward curve of speed and quality in steel production. In 1886 the Hall/Heroult electrolytic process, in one leap, changed aluminum from a hard-won precious metal into a commodity. As material performance came to be scrutinized more closely, the concept of close compositional control in metal production emerged as a new imperative.

Long before this time it must have occurred to someone that a chemical analysis of the product during its production might be very useful, but now the idea took on a new urgency. In 1914 Johnson, who was Chief Chemist at Crucible Steel’s Park Works in Pittsburgh, Pennsylvania, published Rapid Methods for the Chemical Analysis of Special Steels, Steel-making Alloys, and Graphite. (2) This is a volume that reflects the tremendous body of analytical work that had become associated with steel production by the early years of the 20th century.

Laboratories were designed and staffed to perform labor-intensive wet chemical procedures with great efficiency so that in-process hot metal could be adjusted to final compositional limits. Personnel, space, and laboratory equipment were committed to each elemental determination. Common tasks such as sample preparation, the weighing of test portions, and the preparation of stock reagent solutions were typically assigned as entry-level positions. Analysts specializing in carbon or silicon or manganese determinations might, with experience, advance to more involved procedures – perhaps chromium or nickel or molybdenum, especially at mills that produced the new “rustless” grades of steel.

Ores, ferroalloys, coke, and slag required their own separate crew of specialists. Various forms of physical testing of the finished metal were sometimes included in the chemistry laboratory’s responsibilities as well. For a detailed picture of the routine operations in the chemistry laboratory of a large basic Steel Works in this period, see Technical Analysis of Steel and Steel Works Materials by Sisco (1923). (3) Similar situations prevailed in other metal industries. The 1930s and 1940s saw the publication of several important basic texts that served as references for many of these operations. (4–7)

However, the pace of developments in metal production as the century progressed soon made such manpower-intensive laboratories obsolete: the high-frequency vacuum induction furnace was introduced in 1927; the electroslag remelting furnace was developed in 1935; the vacuum arc remelting furnace was in use by 1945; the basic oxygen process was introduced in 1952 and improved a decade later; continuous casting began in 1963 and argon–oxygen decarburization in 1970; and large-scale ladle refining was introduced in 1980. These improvements have made possible the rapid production of new steels and alloys, some with unique properties and some of unprecedented purity.

Analytical developments paralleled these metallurgical advances: the modern ultraviolet/visible spectrophotometer was introduced in 1940; the first direct-reading arc/spark atomic emission spectrometer was marketed in 1950; the first X-ray fluorescence spectrometer in 1955, and the first atomic absorption spectrophotometer in 1960; the direct current plasma emission spectrometer was introduced in 1965 and the graphite furnace atomic absorption spectrophotometer in 1970; the inductively coupled plasma atomic emission spectrometer followed in 1975; and in 1985 the inductively coupled plasma mass spectrometer was introduced. All of these tools, and more, are still in use today. Each has contributed to the speed and efficiency of the metals analysis laboratory.

The production of nearly all commercial alloys has now become an extremely rapid process. Moreover, compositional specifications are commonly stricter than those of the past and often require assurance that deleterious impurities do not exceed a maximum at trace or ultratrace levels. The analytical control function has

kept pace through the judicious application of high-speed instrumentation and automation and by the use of new techniques of extreme sensitivity.

Currently, except in isolated niches, classical wet analytical chemistry is absent from the workplace, replaced by physical instrumental methods. Solution-based techniques remain important in many laboratories, however, and so the science and lore of dissolution have been retained in some quarters – today, such methods are increasingly augmented by developments in closed-vessel microwave oven technology. Flame and electrothermal atomic absorption spectrophotometry and direct and inductively coupled plasma atomic emission spectrometry have become indispensable when time is available to use them (see the article Atomic Absorption and Emission Spectrometry, Solution-based in Iron and Steel Analysis in this section).

However, time is often not available, as in process control applications where 100 tons of molten metal may be “on hold” while the laboratory completes its work. In these instances only work on solid metal samples will do. It is here that the power of certain physical methods and their associated mathematical treatments become evident. Often a pneumatic tube system is used to transport a chilled slug of the molten alloy from furnace-side to the laboratory. The sample is then cut, polished, and analyzed, and the results transmitted to the furnace control room in less than 5 min. There are only a few viable technologies for work at this pace: atomic emission using arc/spark excitation; X-ray fluorescence spectrometry; and thermal evolution techniques (see the article Thermal Evolution Methods for Carbon, Sulfur, Oxygen, Nitrogen and Hydrogen in Iron and Steel Analysis in this section). Both atomic emission polychromators and simultaneous X-ray fluorescence spectrometers are formidable analytical engines, each capable of generating great quantities of data. Sometimes as many as 25 elements are reported in the allotted 5-min interval, and for some complex alloys these may include sizable groups of major, minor, trace, and even ultratrace constituents.

Recently, robotics has been employed in this task with the development of the so-called “container laboratory”. Here, programmed robots prepare the sample, present it to the instrument, and even restandardize the instrument with appropriate reference materials as required (see the article Automation of Analytical Control in the Steel and Metals Industry in this section). Advances in software are leading to heuristic expert systems that can deal with a wide range of alloy compositions by sensing count rates and then selecting among a variety of calibration curves stored in memory. Time-resolved exposures optimize each element channel for the required sensitivity and precision at the relevant concentration range.

In certain metal industries, such as basic steel and aluminum, the robotized laboratory is already becoming commonplace. But unattended automated analysis may not be practical for many types of metal commodities. In particular, it must be emphasized that all the speed and efficiency of this type of automated analysis are based upon the availability of appropriate, accurately certified reference materials, because all such systems are based on comparative methodology. Without reference materials of closely matching composition, none of this tour de force is possible.

Unfortunately, in recent years the availability of reference materials with reliable certified values has become endangered because the infrastructure to certify them has been seriously eroded. It is in those few remaining niches of classical wet analytical chemistry that the best hope for the future lies. It is certainly folly to believe that a certification program based on the use of comparative methodology using alloy reference materials can produce new reference materials with any more than a blurred image of the truth.

Most analysts are aware that accurate sampling is the sine qua non of analytical chemistry because all the conscientious labwork in the world is for naught if the test portion does not exactly reflect the test object. And so it is with metal analysis, where that 100 tons of molten metal may be represented by a 50-g slug, and no less for the furnace charge materials – highly heterogeneous scrap, notoriously segregated ferroalloys, ores, and fluxes – that are bought and sold for use in metal production in enormous lots. Proper sampling is a complex art that must be an important concern of the metal analyst (see the articles Metal Analysis, Sampling and Sample Preparation in and Iron Ore, Sample Preparation and Analysis of in this section).

In many cases the modern metal analysis laboratory is asked to do much more than analyze metal, as difficult a task as that often is. In addition to ore, slag, and refractory materials, typical nonmetal samples include process solutions, such as plating or pickling baths, contact cooling water, furnace gases, and impinger samples from stacks and workplace atmospheres. There also may be inorganic or organic coatings on metal surfaces to identify and quantify, and here specialized techniques often must be brought into play. Instrumental approaches in this area include Fourier transform infrared spectroscopy, Auger spectroscopy, secondary ion mass spectrometry, and others – each a highly specialized field.

It is ironic that, despite all the remarkable advances in analytical science, the metals analyst still remains poised between two worlds. There is no question that advances in physical instrumentation have provided the means to achieve unprecedented accuracy and precision with amazing speed, but at the same time the 3000-year-old
art of fire assay persists as the most reliable means of quantifying certain precious metals. Although silent robots provide the analytical control for vast quantities of steel and aluminum, their performance hinges critically on a diminished store of alloy reference materials, certified by methods developed almost 100 years ago.

The analysis of metals has a rich history, as we have seen, but its future may take leaps and turns that we can now only dimly imagine. High-temperature superconductors, amorphous alloys, shape-memory alloys, directionally solidified and single-crystal alloys, and metal–matrix composites are some of the high-technology material challenges for the analytical chemist today. No one can say which, if any, will be routine commodities in the 21st century. It is, however, reasonable to expect new alloys with imposing compositional specifications. Metallurgical processes are likely to continue to increase in speed as older, inefficient mills and equipment are phased out and replaced. The metals analyst can be expected to meet these new challenges with new analytical tools, such as inductively coupled plasma- and glow discharge mass spectrometry, which are already in use in many metals analysis laboratories.

In this section we have collected a series of articles that represent a picture of industrial steel analysis as it is currently practiced. We have also included some additional topics that reflect the way some of the same challenges are being met for other metal commodities, and with unique methodologies (see articles Nickel Ore and Metals Analysis; Noble Metals, Analytical Chemistry of and Nuclear Magnetic Resonance in Metals Analysis). The reader will find here both the innovative and the routine. It is a picture that conveys a sense of the complexity and depth of this field – an area as demanding and rewarding as any in analytical chemistry.

The use of solution-based atomic absorption spectrometry (AAS) and atomic emission spectrometry (AES) in iron and steel analysis is presented. The article is arranged in different sections dealing with the history relevant to the introduction and the acceptance of these techniques in iron and steel laboratories and their application to iron and steel analysis. A special emphasis is given to the application studies described in the literature for determining the almost forty elements which can be present in steels.

Topics such as sampling and sample preparation, spectrometric measurement, interferences, calibration, and quality assurance criteria are discussed. Finally a brief overview of the standard methods of analysis is presented.

1 INTRODUCTION

Steels are iron-based alloys with a carbon content generally below 2%. In order to be technically competitive on the market with materials such as plastics, aluminum, copper, glass and even cement, steels have to satisfy many property requirements (hardness, tensile and impact strength, electrical and magnetic properties, wear resistance, soundness, fabricability, formability, surface finish, cleanliness, corrosion resistance in a host of different environments, resistance to failure by hydrogen embrittlement, stress corrosion, fatigue, etc.).

Although the chemical composition is not a real requirement, nevertheless it is the vital starting point from which any desired property or group of properties can be consistently produced. By varying the chemical composition and applying various thermal treatments, different properties can be achieved and, therefore, different grades of steel produced. Plain carbon steel is converted into special steel when sufficient concentrations of other elements are introduced to alter the properties significantly (e.g. up to 3% nickel, chromium and/or molybdenum, vanadium, etc., to produce “low-alloy steels” for engineering purposes; up to 9% nickel or chromium to form “medium-alloy steels”, etc.).
“Stainless steels” are one of the best known special steels. They are made by the addition of at least about 11% chromium. This minimum confers tarnish- and corrosion-resistance in gaseous and liquid media that would attack plain carbon steels.

There are over 200 types (grades) of stainless steels, so that the American Iron and Steel Institute (AISI) uses a three-digit system to separate standard grades of wrought stainless steels into four general classes, based on composition: series 200 (chromium, nickel, and manganese), series 300 (chromium and nickel), series 400 (chromium) and series 500 (low chromium).

In iron and steel production it is mandatory to keep the content of different elements under rigorous control during all transformation steps from raw materials to finished products in order to be sure that the composition of the steel falls within an established range of acceptability.

Chemical composition control not only concerns steel during its production but also all the other materials related to the process. These include fuels, oils, raw materials such as iron ores, ferroalloys and steel scraps, waters, pickle liquor, lubricants, effluents, wastes.

In the early days of industrial steel-making, chemical analysis played a minor role in the production. However, fairly soon, it was obvious that knowledge about the chemical composition had to be known during the processing. For example, when the Bessemer process was introduced around 1860 it became necessary to have better control of the carbon content during production and the need for fast carbon determination was increased.

Chemical laboratories grew quickly in importance. All the analyzes were based on wet chemical methods such as gravimetry, potentiometry, titrimetry, ultraviolet and visible spectrophotometry. The complexity of the analysis became very high when production of stainless steels started in the early 1900s.

In the mid 1940s the first simultaneous emission spectrometers were able to determine a large number of elements in solid steel samples. Another breakthrough in steel analysis came in the 1950s when the X-ray fluorescence technique was introduced.

Since that time analytical chemistry in iron and steel plants followed two directions: high-speed spectroscopic methods were used for the production control, while classical wet methods were used for the control of the finished products, for the certification of reference materials necessary for the calibration of the spectrometric apparatus and for the analysis of all those materials not directly linked to the speed of the production process or not detectable (for size, quantity, or concentration) by instrumental methods.

The determination of element concentrations by wet methods changed drastically at the end of the 1960s when flame atomic absorption spectrometry (FAAS) was introduced in iron and steel laboratories in order to satisfy the pressing requirements of sensitivity, accuracy, speed and low cost.

Early in the history of steel-making, trace elements were totally neglected but in the 1970s it was discovered that some elements, present in low concentration in steels, like Pb, Bi, As, had detrimental effects on the mechanical properties such as hardenability, hot workability, creep resistance, etc. It was also found that some elements, such as Ca, Mg, Zr, Ce had positive effects on the properties even in very low concentrations. As the need for trace analysis increased, it became clear that the sensitivity of FAAS was not sufficient and extraction procedures employed prior to instrumental determination were necessary.

This obstacle was overcome with the adoption in the 1970s of electro thermal atomic absorption spectrometry (ETAAS).

At the end of the 1970s AES with plasma sources, owing to its linear calibration over wide concentration ranges, became the preferred methodology for major and minor element determination. A few laboratories are attempting to extend the detection limit (DL) of conventional plasma AES by employing preliminary solvent extractions, ion exchange, precipitation techniques, or linking ion chromatography to plasma AES to circumvent spectral interferences. Volatilization of the analyte compound followed by direct introduction of the volatile species into the plasma is another means to increase the sensitivity and decrease the interferences.

## 2 HISTORY

FAAS as an analytical tool for chemical analysis was introduced by Walsh$^{1–2}$ and Alkemade and Milatz$^3$ in the 1950s. Walsh suggested that measurement of the absorbance at the peak of the absorption line profile would give a linear relationship with concentration over a wide range of absorbance values.

Since then FAAS has become one of the best and most widely used analytical methods for the determination of major and minor constituents. FAAS concerns the determination, in liquid or dissolved samples, of concentrations of elements with atoms capable of absorbing radiation within the optical spectrum range.

The sample is converted into an atomic vapor by use of an air/acetylene or a nitrous oxide/acetylene flame. The number of atoms capable of absorbing any particular wavelength of transmitted light is proportional to the concentration of these atoms in the optical path in the flame. FAAS relies on measuring the peak absorbance of
a spectral line by using a spectral light source emitting a sharp line.

In its simplest form the radiant source employed is a hollow cathode lamp emitting radiation from excited atoms of the same element as that to be determined. This radiation, in the form of a line spectrum, is absorbed by the sample which has been atomized at 2000–3000°C.

The resulting spectrum of the source radiation is one with lines of reduced intensity, the magnitude of the reduction being proportional to the concentration of the element in the atomized vapor. A monochromator is used to select a single wavelength for examination and changes in the intensity of this wavelength are related to different analyte concentrations.

FAAS gained popularity in iron and steel laboratories for the following reasons:

- capability of analyzing most elements
- good sensitivity
- ease of handling
- only a few interferences.

The replacement of the flame by an electrothermal sampling device improved the DL by one to three orders of magnitude. Among the electrothermal atomization techniques, graphite furnace atomic absorption spectrometry (GFAAS) is most popular.

This technique is ideal for ultratrace determination and requires only a few microliters or micrograms of a sample. Originated by Massman and L’vov, the technique employs a graphite furnace to produce ground-state atoms by rapid volatilization of a small quantity of sample. The improved sensitivity is attributed partly to the fact that the residence time of the atoms in the light beam is much longer in the furnace than in the flame.

The graphite furnace can be used with almost all atomic absorption spectrometers. The energy required for atomization is supplied by applying a high electrical current through a graphite tube, where the sample has been placed. The furnace is located in the sample compartment so that light from the light source passes through the graphite tube. When the furnace is fired, the generated atomic vapor absorbs light from the source. The absorption signal is transient and a peak-shaped signal is produced as the atom concentration within the furnace rises, and then falls. Either peak height or peak area may be used for quantitation. As sample components can affect the rate of atom formation and hence the signal shape, integration over the peak area could result in better accuracy compared to peak height evaluation. A programmable power supply provides precise control of temperature programming for the drying and atomization steps. Micro amounts of solid steel samples can be analyzed directly without prior dissolution. Usually in GFAAS a measured volume of the test sample solution or a weighed mass of the test sample is introduced into the graphite atomizer. For this reason the atomization signal is proportional to the analyte mass in the test sample portion and not to its concentration.

The low cost of the GFAAS and the low limits of detection render this technique competitive for trace and ultratrace analysis in comparison with new techniques devoted to ultratrace analysis, such as inductively coupled plasma/mass spectrometry (ICP/MS).

Plasma AES, although introduced in 1964 by Greenfield and Fassel, has found application in iron and steel laboratories only since 1980, after a certain number of papers showed its good performance in the analysis of steel.

The reasons for the introduction of this technique in iron and steel laboratories were:

- very large dynamic range
- very low noise signal
- most elements can be measured
- fast
- high sensitivity
- linear calibration over wide concentration ranges
- fundamental calibration from pure reagents
- ability to determine a programme of elements simultaneously.

In atomic spectrometry the absorption and emission of energy can take place with atoms and ions only in discrete quantities which are characteristic for each element. In emission spectrometry the atoms or ions are excited thermally and the number of photons emitted during relaxation is measured. The identification of the elements takes place by means of the wavelength of the radiation, while the concentration of the element is proportional to the intensity of the radiation. Since all the elements present are excited at the same time and therefore emit radiation simultaneously, it is possible to determine several elements at the same time.

In DCP (direct current plasma) and ICP (inductively coupled plasma) spectrometry the excitation takes place in a plasma.

ICP is generated in the following way: a gas, usually argon, flows through a system of three concentric tubes surrounded by a coil. A high-frequency alternating current is sent through the coil. Some charged particles are introduced into the gas by means of a spark discharge. They are accelerated into the electromagnetic field of the coil and can ionize other argon atoms by means of collisions. These ions are also accelerated and they can again ionize atoms or recombine to atoms by recombination. This produces a chain reaction which leads within a fraction of a second to a state of equilibrium whereby the number of ionization and recombination reactions are
equal to each other. In the resulting plasma approximately 1% of the argon atoms are ionized and the gas has a temperature of about 8000–10 000 K.

If a solution is introduced into the plasma, the solvent will evaporate, after which the compounds present will melt, liquefy, evaporate and decompose into the constituent atoms. These atoms may be ionized. Both atoms and ions will be excited. The excited species will revert to lower energy state, whereby the absorbed energy will be released by the emission of photons. The wavelengths of the emitted radiation are characteristic for each element. In addition to this line spectrum there is a background which is caused primarily by recombination radiation and molecular emission bands. The spectrum can be analyzed by means of the dispersion of the radiation in a spectrometer. The intensity of radiation at a given wavelength is measured by means of a photomultiplier tube. A correction is made for background emission. The net intensity is proportional to the concentration of the analyte element over a range of typically up to six decades. The proportionality factor depends to a great extent on the analytical wavelength used and on the type and adjustment of the instrument which is used.

In the case of the DCP source the aerosol hits the surface of the plasma in the centre of three branches. Due to this the temperature available is lower than in the ICP and will be about 6000 K.

Plasma produces higher temperatures than chemical flames. These higher temperatures allow the dissociation of many types of compounds, allowing a wider range of determination than FAAS.

3 IRON AND STEEL APPLICATION

In steel and iron determination the analyst must cope with extreme differences in element concentrations, amounting to as much as six or seven orders of magnitude. From the analytical chemistry point of view, steel can be classified in three categories, in which the concentration ranges of elements are given in Table 1.

AAS (flame and electrothermal sources), as well as plasma AES, are exploited in iron and steel analysis for determining practically all the elements of the periodic table, excluding the inert gases, halogens, H, C, N, O.

The selection of AAS or plasma AES depends on the type of analysis required (the element, its concentration, the matrix composition, accuracy and uncertainty, cost of analysis) and the exigencies of the laboratory and how often the instrument is to be used on a routine basis. Plasma AES, for example, is used in routine methods when determining elements at high levels (>6%) with a precision (repeatability) of 0.5–0.6%.

When multiple elements are required on one sample, inductively coupled plasma/atomic emission spectroscopy (ICP/AES) is preferred, owing to the multielement capacity of AES.

For the determination of a single element, FAAS is quicker and more cost effective. Plasma AES is clearly superior to FAAS in the dynamic range covered and this allows a large range of elements be determined on a single solution preparation without any dilution. A few elements such as B, Ce, La, Nb, P, Pb, Pr, Sn, Ta, Ti, V, W and Zr have good DLs in the ICP but in FAAS sensitivities are poor. Usually, for high-precision trace analysis, electrothermal sources are required.

The concept of trace level in steel and iron has changed with time as the knowledge of the properties of elements increased. Today, trace analysis in metals can be defined as analysis involving element concentrations up to 50 µg g⁻¹ (ppm) of sample. This means that the real concentration in the solution will be less than 0.5 µg ml⁻¹, with the solution containing less than 1% (m/m) of solid sample.

A comparison of the current DL for pure elements in acid solution for the ICP/AES, FAAS and graphite furnace techniques is reported in Table 2.

The limit of quantitation (LOQ) in steel analysis is generally 10–100 DL.

In the literature, interferences from the matrix, chemical and ionization effects and background interferences were documented along with procedures for eliminating or compensating for them. The main strengths of these techniques today are the availability of proven methodologies and reference standards for almost all the elements of the periodic table.

One of the first papers concerning steel analysis was published in 1962 by Belcher and Bray(8) which described a procedure for magnesium determination. Butler, Fassel, and Kniessley(9) were the first to report on analytical ICP work for iron and steels and related alloys. With the financial support of the Commission of the European Communities many application studies have been carried out in the field of the analysis of steels and related materials in order to evaluate the capability of flameless AAS(10–14) and plasma spectrometry(15–18) as techniques to be used routinely in iron and steel laboratories. As far as plasma spectrometry is concerned, a line coincidence table for 40 elements that do not show any spectral interferences from the matrix up to a concentration of 5 mg ml⁻¹ of Fe has been worked out by Wittmann.(19) Reviews on the application of AAS to the analysis of iron and steel alloys were prepared by Ohls and Sommer,(20) Stafilov(21) and Kobayashi.(22) Bloedorn,(23–24) Ambrose,(25) and Fujimoto(26) presented a review of improvement of the reproducibility, sample pretreatment and calibration in ICP/AES. This section
provides a survey of a few of the most interesting application studies described in the literature for the iron and steel analysis by AAS and AES solution-based spectrometry with reference to each element of the periodic table.

### 3.1 Aluminum

Aluminum was determined in low-alloy steel by Klein and Rains. Specimen preparation, calibration standard preparation, analysis condition and instrument parameters were investigated.

The determination of aluminum was carried out by FAAS using a nitrous oxide–acetylene flame, with no interferences, by Headridge and Sowerbutts, and Manning. The iron concentration was matched. Brivot determined aluminum by FAAS and by spectrophotocolorimetry. Shaw and Ottaway, Yu and Cui, Atsuya, and Zykova determined trace amounts of aluminum in steels by GFAAS. Persson also determined aluminum in steel by GFAAS. The sample was dissolved in hydrochloric acid/nitric acid and ammonium sulfate was added to eliminate the influence of hydrochloric acid. The iron content in the sample reduced the sensitivity by about 20% and was therefore matched in the reference solution.

Collin analyzed the various nonmetallic phases in steel which have considerable influence on the physical and mechanical properties. Kobayashi and Naka carried out the determination of acid-soluble and
Traces of antimony were determined by ICP/AES by Zhang(52) by solvent extraction in methyl isobuthyl ketone.

### 3.3 Arsenic

The hydride technique was applied by Fleming(44) and the graphite furnace by Barnet,(47) Del Monte Tamba(50) and Bettinelli.(49)

The method for the determination of arsenic in stainless steel by ICP/AES at the wavelength 228.81 nm was described by R. Diemiaszonek.(53) Ward,(42) Hughes(15) and Zhang(52) analyzed arsenic at λ 193.70 nm. Mendez Garcia(54) determined arsenic by ICP/AES by direct introduction of arsenic into the plasma. Arsenic from the sample solution was extracted on-line as AsI3 into a xylene solution. The xylene extract continuously reacting with sodium borohydride in dimethylformamide and acetic acid generated AsH3 which was introduced into the plasma.

Arsenic in austenitic steel was determined by Nakayama.(55) He decomposed the sample in a mixture of HCl and HNO3, filtered and separated the solution obtained in an anion exchange chromatographic column; the resulting eluent was treated with a mixture of NaBH4 and HCl, and then subjected to ICP/AES. The determination of hydrides of As in steels was carried out by Ozaki(56) by coupling a polytetrafluoroethylene phase-separator layer to an ICP atomic emission spectrometer. Weltz(51) developed a method for the determination of arsenic in steel using flow injection hydride generation atomic absorption spectrometry (FI/HGAAS) and L-cysteine as a reducing and releasing agent.

### 3.4 Barium

This minor element in most iron oxides is usually lost in the refining process of low-alloy iron casting and steels. The determination of barium by FAAS was described by Rains,(28) Belcher(57) and David,(58) According to David(58) the nitrous oxide/acetylene flame has been shown to be very useful. In this flame, barium is highly ionized and an ionization suppressant must be added.

Barium was determined by ICP/AES by Hughes(15) at the wavelength 455.40 nm.

### 3.5 Bismuth

Fleming,(44) Weltz(59) and Vanloo(60) determined bismuth by applying the hydride technique, while Barnett(47)
employed electrothermal atomization. GFAAS was used by Bettinelli\(^{(49)}\) and also by Dulski\(^{(61)}\) who used spiked samples for calibration. Del Monte Tamb\(\ accents\(^{(12,50)}\) Takada\(^{(62)}\) and Frech\(^{(63)}\) determined bismuth on solid samples. Cadore\(^{(64)}\) developed a method for the determination of trace amounts of bismuth using flow injection and AAS with hydride generation. A comparison between flow injection hydride generation AAS and GFAAS was carried out by Bettinelli.\(^{(65)}\)

The method for the determination of bismuth in stainless steel by ICP/AES at the wavelength 306.77 nm was described by R. Diemiaszonek.\(^{(53)}\) Zhang\(^{(52)}\) determined bismuth in iron and steel by solvent extraction and ICP/AES.

### 3.6 Boron

The method for the determination of boron in stainless steel by ICP/AES at the wavelength 249.68 nm was described by R. Diemiaszonek.\(^{(53)}\) Boron was determined by Hughes\(^{(15)}\) by ICP/AES using \(\lambda\) 249.77 nm and by Belliveau\(^{(66)}\) using a multielement de plasma emission spectrometer. Boron down to 1 ppm was determined by Baena Libera\(^{(67–69)}\) and by Chiba\(^{(70)}\) by ICP/AES using a solvent extraction approach. Lopez Molinero\(^{(71)}\) set up a method for determining acid soluble and acid insoluble boron in steels based on ICP/AES.

### 3.7 Cadmium

Trace of cadmium were directly determined by Liu\(^{(72)}\) in stainless steels by platform GFAAS after dissolution of the sample in aqua regia, and redilution in 1 + 1 HNO3. The detection range is 1.10 \(\mu\)g g\(^{-1}\) and the relative standard deviation is 9.3–14.3%. Barnett\(^{(47)}\) determined cadmium by GFAAS, applying the analyte addition technique, while Del Monte Tamb\(\ accents\(^{(50)}\) and Lundberg\(^{(73)}\) analyzed cadmium by GFAAS using solid samples.

Cadmium was determined by ICP/AES at wavelength 226.50 nm by Hughes.\(^{(15)}\)

### 3.8 Calcium

Calcium in steels by AAS was determined by Reins,\(^{(28)}\) Belcher,\(^{(74)}\) and Tugane.\(^{(75)}\) Headridge\(^{(76)}\) determined trace amounts of calcium in stainless steel by solvent extraction followed by AAS. Traces of calcium were determined by carbon furnace by Glene\(^{(77)}\) and Alvarado.\(^{(78)}\)

Hughes\(^{(15)}\) determined calcium by ICP/AES at \(\lambda\) 315.89 nm. Metallic and chemically bound calcium in steels was determined by Golloch\(^{(79)}\) by ICP/AES employing electrothermal atomization.

### 3.9 Cerium

Cerium was determined in steel by ICP/AES by Butler,\(^{(9)}\) using the wavelength 456.2 nm, by Diemiaszonek\(^{(53)}\) using \(\lambda\) 413.76 nm and by Hughes\(^{(15)}\) at \(\lambda\) 395.25 nm.

### 3.10 Cobalt

Sprague,\(^{(80)}\) Cobb,\(^{(81)}\) Gregorczyk\(^{(82)}\) and Wycislik\(^{(83)}\) determined cobalt by FAAS. Cobalt in tool steel was analyzed by Knight,\(^{(84)}\) while trace cobalt in steel was analyzed after chloroform extraction of its 1-nitroso-2-naphthol complex by Eskell.\(^{(85)}\) Cobalt was analyzed by ICP/AES by Ward\(^{(42)}\) and Hughes\(^{(15)}\) at \(\lambda\) 228.62 nm.

### 3.11 Chromium

Chromium was analyzed by FAAS by Kinson,\(^{(86)}\) Barnes,\(^{(87)}\) Gomez Coedo,\(^{(88)}\) Thomerson,\(^{(89)}\) Ottaway,\(^{(90)}\) Cobb,\(^{(91)}\) Pandly,\(^{(92)}\) Grimaldi,\(^{(93)}\) Gregorczyk,\(^{(94)}\) Husler,\(^{(95)}\) Sire,\(^{(96)}\) Wycislik,\(^{(78)}\) and Fogg\(^{(97)}\) used the masking of iron with fluoride in extractive atomic absorption determination of chromium in steels. Chromium was analyzed by ICP/AES at \(\lambda\) 357.8 nm by Butler,\(^{(9)}\) at \(\lambda\) 302.43 nm by Diemiaszonek,\(^{(52)}\) at \(\lambda\) 267.72 nm by Ward\(^{(42)}\) and Hughes\(^{(15)}\) and at \(\lambda\) 350.2 nm by Belliveau\(^{(66)}\) and Gomez Coedo.\(^{(98)}\) Souza\(^{(99)}\) determined chromium in steels by plasma AES after electrodissolution in a flow injection. AAS and ICP/AES were used by Chin\(^{(100)}\) for the determination of chromium in low-alloy steel armor.

### 3.12 Copper

Sprague,\(^{(80)}\) Wycislik\(^{(78)}\) and Kinson\(^{(101)}\) determined copper by FAAS. They found that the determination of copper is influenced both by the acid content and the iron concentration, so they matched the reference solution correspondingly.

Copper was determined by ICP/AES at \(\lambda\) 324.7 nm by Butler,\(^{(9)}\) Ward,\(^{(42)}\) and Hughes.\(^{(15)}\)

### 3.13 Lanthanum

The method for the determination of lanthanum in stainless steel by ICP/AES at the wavelength 398.8 nm was described by Butler.\(^{(9)}\) R. Diemiaszonek\(^{(53)}\) used \(\lambda\) 408.67 nm.

### 3.14 Lead

Lead occurs as a residual element in steel and can cause catastrophic failure in cast iron. Gluc\(^{(102)}\) determined lead by AAS in the range 0.0005–0.04%. T.C Rains,\(^{(28)}\) Barnett,\(^{(47)}\) Shaw and Ottaway,\(^{(103)}\) Dulski and Bixler,\(^{(61)}\)
Bettinelli, (49) Frech, (104–106) and Mile (107) have described analytical methods for the determination of lead in steel by GFAAS. Special procedures were developed to overcome analyte losses due to chloride during the charring step. A few authors recommended a separation to remove the lead from the iron matrix prior to the determination. Fleming (44) determined lead by the hydride technique. The analysis of the solid sample by GFAAS was carried out by Del Monte Tamba, (12) Andrew (108) and Frech. (63)

Butler et al. (9) and Zhang (51) determined lead by ICP/AES using the wavelength 405.7 nm.

3.15 Magnesium
Magnesium is present in steel as a residual element. In 1962 Belcher (8) developed a procedure which is still frequently used today. Some 1 g of sample is dissolved in 30 mL of 1+1 hydrochloric acid and oxidized with 5 mL nitric acid. The solution is evaporated to dryness, mildly heated for a further 5 min, taken up in 10 mL hydrochloric acid and then diluted with strontium chloride solution. (2) The determination of magnesium is carried out by FAAS using either an air/acetylene flame or a nitrous oxide/acetylene flame. Belcher, (57) Rains, (26) and Sprague (80) determined Mg by graphite furnace. Hughes (15) determined magnesium by ICP/AES at λ 279.55 nm.

3.16 Manganese
Manganese was determined by FAAS by Klein, (27) Brivot, (31) Sprague, (80) Gregorczyk, (82) Knight, (84) Husler, (85) Sire, (96) Wycislik, (83) Belcher, (109) Atsuya, (110) Hubbold, (111) and by ICP/AES, at λ 403.0 nm by Butler (9) while Hughes (15) and Ward (42) used λ 257.61 nm, as did Belliveau (66) that determined manganese by dc AES. Souza (99) proposed for its determination a flow injection elutriodissolution procedure. Chin (100) determined manganese both via AAS and ICP/AES.

3.17 Mercury
Mercury was determined by ICP/AES at λ 253.65 nm by Hughes. (15)

3.18 Molybdenum
David (112) showed that molybdenum absorption is very dependent on the air to acetylene ratio. A serious suppression of absorption happens when manganese, calcium and strontium are present. An acetylene/air flame was also used by Gregorczyk (82) for determining molybdenum in low- and medium-alloy steel, while Thomerson, (89) Kirkbright (113) and Klein (27) used a nitrous oxide/acetylene flame. FAAS was applied for molybdenum determination by Grimaldi, (83) Hussler, (95) Wycislik, (83) Endo, (114) Goto (115) and Wada. (116) Knight (84) determined molybdenum in tool steels. A preliminary extraction with benzoinoxine–methyl isobutyl ketone (MIBK) was carried out by Castillo. (117) Traces of molybdenum in cast iron have been determined by Gu (118) by FAAS extraction from 60% (v/v) HCl with ethyl-N-laurylthioacetate (ELTA) into butylacetate and back extraction with 1% (v/v) ammonium hydroxide. Bodrov and Nickolaev (119) determined molybdenum in steels using a L’equiv furnace and found no interferences other than from a high concentration of titanium and niobium. Molybdenum was analyzed by ICP/AES at λ 203.03 nm by Ward, (42) at λ 287.15 nm by Hughes (15) and at λ 281.6 nm by Belliveau (66) and Chin. (100).

3.19 Nickel
Nickel was analyzed by FAAS by Klein, (27) Kinson, (120) Sprague, (80) Gregorczyk, (82) Knight, (84) Sire, (96) Wycislik, (83) Welz, (121) and by ICP/AES at λ 351.5 nm by Butler, (9) at λ 300.36 nm by Demiaszonek, (53) at λ 231.60 nm by Hughes (15) and Ward. (42)

Souza (99) determined nickel in ferritic stainless steels by ICP/AES.

3.20 Niobium
Schiller (122) determined niobium at concentrations below 0.3% in low-alloy steels by FAAS, while Thomerson (123) determined niobium down to 0.05%. Niobium was also analyzed by Martin using FAAS. (124)

Niobium was determined by ICP/AES at λ 405.8 nm by Butler, (9) at λ 313.08 nm by Ward, (42) and at λ 309.42 nm by Gomez Coedo. (41)

3.21 Phosphorus
Phosphorus was determined by GFAAS by Whiteside (125) and Welz. (126) Welz used the Zeeman background correction.

The method for the determination of phosphorus in stainless steel by ICP/AES at the wavelength 253.40 nm was described by R. Diemiaszonek. (53) Several emission lines were analyzed by Wallace. (127) λ 214.91 nm was used by Ward. (42) λ 178.28 nm by Hughes. (15) Phosphorus in steel was isolated by ion-exchange chromatography and analyzed by ICP/AES by Demidova. (128)

3.22 Praseodymium
Praseodymium was determined by ICP/AES at λ 417.9 nm by Butler, (9) while Hughes (15) used λ 180.73 nm.
3.23 Rare-earth Elements

There is only a limited amount of reported work on the rare earth elements, although many absorption lines have been observed. Generally, their determination is carried out by spectrophotometry. Total rare earths in steel were determined by Zhao et al. by an indirect method based on the reversal of the phosphorus suppression of magnesium absorption intensity.

3.24 Selenium

Peterson determined selenium free of interferences in stainless steels in the range 0.2–0.5% by dissolving the sample in hydrochloric acid and treating it with sulfuric acid/phosphoric acid.

Knight and McCarthy determined silicon by ICP/AES. For the direct determination of silicon in cast stainless steels in the range 0.2–0.5% by dissolving the sample in hydrochloric acid/nitric acid and treating it with sulfuric acid until solution is complete. Then 10 mL 12% nitric acid and 0.5 g sample is warmed with 25 mL of 1.5 M sulfuric acid. The iron concentration was matched.

3.25 Silicon

Knight and McCarthy determined silicon by ICP/AES at 288.16 nm by Ward, and at 251.61 nm by Hughes and Dorado Lopez. Belliveau determined silicon by de plasma emission spectrometry.

3.26 Silver

Silver is a deleterious element in steel and can be determined by FAAS with an air/acetylene flame as low as 0.0002%. Hofton determined silver after extraction of dithizionate in MIBK. Traces of silver were determined by GFAAS by Dulski. Aziz Alrahman determined silver on solid samples by GFAAS. Hughes applied GFAAS.

3.27 Sulfur

Sulfur was determined by Mendez Garcia in low-alloy steel down to 20 ppb by mixing an alkaline solution of the sample with 6 M hydrochloric acid and injecting the generated hydrogen sulfide directly into the plasma.

3.28 Thallium

Thallium was determined by GFAAS by Dulski. He found that a direct determination by the graphite furnace technique brought a saving of time and provided satisfactory results. Calibration was carried out through spiked samples.

3.29 Tantalum

Tantalum was determined by FAAS by Obrusnik. A concentration of 0.0012% of tantalum was determined at the wavelength 240.06 nm by DCP/AES by Belliveau and by ICP/AES by Ward and Danzaki at 240.06 nm. Hughes and Diemiaszonek determined tantalum at 295.19 nm.

3.30 Tellurium

Marceg determined traces of tellurium by precipitating with tin (II) chloride and extracting the diethylthio-carbamate complex with pentylacetate, while Barnett described a procedure without prior extraction where the sample is dissolved in a mixture of HNO3 and H2SO4. Background correction was used. Fleming determined tellurium by the hydride technique while Dulski and Bettinelli adopted GFAAS.

Tellurium was determined by ICP/AES at 238.58 nm by Hughes.

3.31 Tin

Fleming and Gluc determined tin in steels by the hydride technique while Barnett, Ratcliffe, Del Monte, Xuan and Bettinelli applied GFAAS. Weltz accurately determined tin in steels in the range 0.008–0.1% by flow injection hydride generation AAS with matrix-free standard solutions for calibration.

Tin was analyzed at wavelength 326.23 nm by DCP/AES and by ICP/AES at 242.17 nm by Diemiaszonek. Zhang determined trace amounts of tin by ICP/AES after solvent extraction with MIBK.

3.32 Titanium

Headridge determined titanium in the nitrous oxide/acetylene flame with no interferences. Only the iron concentration was matched.

2 g of steel were dissolved in a mixture of HCl and HNO3. After the solution was cooled, potassium and lanthanum chloride were added and the solution obtained was diluted to the mark in a 100-mL volumetric flask. The determination of titanium in high-alloy steels and
iron sand was carried out by Negishi. Titanium has been preconcentrated by extraction from 0.1 HCl/0.1 M HF with a solution of Amberlite LA2 in benzene followed by back extraction into the aqueous phase with 1.2 M HCl/0.5 M HF. Mo, V, and Zr interfere. Titanium in stainless steel by ICP/AES was determined by Hughes. Vanadium by ICP/AES was determined by Hughes and Ward. Okamoto extended the DL of conventional ICP for titanium determination employing electrothermal atomization.

3.33 Tungsten

Tungsten was analyzed by FAAS by Husler and Tindall. They pulverized the samples and dissolved them slowly in concentrated hydrochloric acid in a water-bath at 60–70°C. Musil reduced tungsten with tin(II)chloride and extracted the thiocyanate complex into MIBK. The organic phase was nebulized directly into a nitrous oxide/acetylene flame. Butler et al. and Diemiaszonek determined tungsten by ICP/AES using the wavelength 400.8 nm. Ward used \( \lambda \) 207.91 nm.

3.34 Vanadium

Vanadium was determined by Klein. 2 g of steel were dissolved in a mixture of HCl and HNO₃. After the solution was cooled, potassium and lanthanum chloride were added and the solution obtained was diluted to the mark in a 100-mL volumetric flask. The determination of vanadium can be carried out in a nitrous oxide/acetylene flame with no interferences when the iron concentration is matched. Husler used a nitrous oxide/acetylene flame. After the addition of iron to the reference solution and potassium as ionization buffer, the determination in this flame was free of interferences. FAAS was used also by Sire, Knight and Husler determined vanadium in tool steels and Del Monte Tamba determined vanadium by GFAAS. Vanadium by ICP/AES was determined by Hughes using wavelength 311.07 nm. Ward used \( \lambda \) 292.40 nm, while Gomez Coedo used \( \lambda \) 309.31 nm. Okamoto extended the DL of conventional ICP for titanium determination employing electrothermal atomization.

3.35 Yttrium

Yttrium was determined by ICP/AES by Karandashev in pure iron and low-alloyed steel by means of extraction through columns of tetraphenylmethylendiphosphine oxide stationary phase on styrene-divinylbenzene macroporous copolymer support.

3.36 Zinc

Frech and Takada determined zinc on solid samples by GFAAS. Zinc was determined by ICP/AES at \( \lambda \) 213.86 nm by Hughes.

3.37 Zirconium

Stelze analyzed zirconium in low-alloy steel by FAAS. Most of the metals at 1000 mg L⁻¹ or higher concentration level interfere with the zirconium absorbance signal. 0.001% of zirconium were analyzed at the wavelength 349.62 nm by DCP/AES by Belliveau and at \( \lambda \) 349.6 nm and at \( \lambda \) 343.82 nm by ICP/AES. Butler determined zirconium by GFAAS. Gomez Coedo, Ward and Hughes used \( \lambda \) 339.20 nm.

4 SAMPLING AND SAMPLE PREPARATION

Iron and steel are sampled from the liquid for process control and as solids for specification checks. In this paper only the sampling of the steel product is considered. Sampling and preparation of the iron and steel samples for the determination of chemical composition are carried out in accordance with the International Standards Organization (ISO) 14284. Samples must be sound, free from blow holes and representative of the mean chemical composition of the sample product. They must be free from surface coatings and from moisture, dirt or other forms of contamination. If necessary, the surface of the metal must be degreased by means of a suitable solvent, making sure that the degreasing process does not affect the correctness of analysis. Chips are obtained by machining (drilling, milling, turning or punching). Tools, machines and containers used during the preparation of the sample must be cleaned beforehand to prevent any contamination of the sample. Machining has to be carried out in a such a way as to avoid overheating. Chips must be thoroughly mixed before weighing the test portion, by rolling or gently tumbling the container. Where machining of the sample to obtain chips is impractical, it can be cut or broken into pieces. These pieces can be crushed using a percussion mortar or a vibratory grinding mill. AAS and AES are predominantly techniques for the analysis of liquid or dissolved samples. Steel and iron samples, therefore, usually must be brought into solution.

However, procedures have been described and techniques are available for the direct analysis of solid samples. Iron and steel are usually brought into solution using an acid digestion with hydrochloric acid, nitric acid or...
with their mixture in varying proportions, sometimes followed by a perchloric, phosphoric or sulfuric acid fuming, or a fusion. The type of sample pretreatment is governed by the analytical task. For example, steels with high content of tungsten always require the addition of phosphoric acid after the treatment with HCl/HNO₃ mixture.

In general, an acid digestion is preferred because it does not increase the total dissolved solids content in the test sample solution. However, a few test samples are not completely dissolved by an acid digestion because silicates and other refractory compounds such as oxides, carbides and nitrides may remain undissolved.

If the total content of all analyte is of interest a fusion with sodium carbonate, lithium metaborate is often required, usually followed by an acid treatment with nitric or hydrochloric acid.

In general, care should be taken that the total dissolved solids content in the test sample solution is not too high in order to avoid interferences by concomitants. The viscosity of solution can have a significant effect on nebulization efficiency. The maximum tolerable dissolved solids content depends on the type of matrix and on instrumental details, such as the nebulizer burner system and the means of solution introduction. For example, much higher total dissolved solids contents can be tolerated if the test sample solution is introduced via a carrier liquid (flow injection analysis) instead of by conventional aspiration.

In the literature many acid mixtures for steel dissolution are reported. For example, Beyer(154) warmed about 500 mg of sample with 10 mL of 1 + 1 hydrochloric acid and added concentrated nitric acid drop by drop until all soluble metal had been dissolved. Kinson and Belcher(120) found that tungsten steel can be better dissolved in phosphoric acid/hydrofluoric acid. Husler(95) dissolved tool steels in nitric acid/hydrofluoric acid and Schiller(122) employed the same acid mixture for dissolving niobium in low-alloy steels.

When low-alloy steel has to be analyzed by FAAS it can be brought easily into solution also with 5% sulfuric acid and 0.5 g of ammonium persulfate. This type of acid has to be avoided when GFAAS is used. Dissolution in nitric acid is preferred. Hydrochloric acid must also be avoided owing to the problems which may be encountered from the loss of volatile chloride species. If chloride is present, excess nitric acid has to be added to the sample.

The analytical procedures reported in the literature for determinations by plasma AES do not differ drastically, since this technique requires approximately similar conditions (in particular the salt content of the solution and the amount of sample that can be fed into the plasma in a unit of time (minute)).

A simple procedure for dissolving plain carbon steel when silicon and zirconium have to be analyzed by plasma AES is as follows.

0.5 g of sample is gently warmed in a mixture of hydrochloric acid and nitric acid until the reaction ceases. The solution obtained is transferred into a 100 mL polyethylene volumetric flask, cooled and a small amount of hydrofluoric acid is added. The flask is immediately closed. After a few minutes the solution is brought up to the mark with distilled water. For such hydrofluoric acid-bearing solutions the plasma instrument has to be equipped, with an alumina torch.

While dissolution is facilitated by heating, care must be taken during the thermal treatment because some analytes may be lost as volatile species. Volatile loss during acid dissolution can be prevented or minimised by carrying out the digestion in a closed pressure vessel or by boiling under reflux. Also, in steps involving ignition and dry ashing, volatile elements and compounds are particularly prone to complete or partial escape. The analyte may also be lost by precipitation, coprecipitation, or sorption on container walls.

At the end of 1980s closed vessel systems designed to be rapidly heated by microwave energy had been adopted. Microwave heating is used with closed vessels because of increasing boiling temperature and hence increasing efficiency of the dissolution. For example, the performance of nitric acid is enhanced considerably in closed microwave vessels. The boiling point reaches 176 °C at about 75 psi, substantially increasing oxidizing power and decreasing reaction times. A study carried out with the financial aid of the European Commission set up steel dissolution procedures using microwave ovens(155).

Most steels, with tungsten content below 5%, can be dissolved in such vessels with a very small amount of hydrochloric, nitric and hydrofluoric acid.

Steel with a tungsten content higher than 5% can be dissolved in a microwave oven by treating 0.25 g of sample with 5 mL of hydrochloric acid, 2 mL of nitric acid, 2 mL of phosphoric acid, 5 mL of water and 2 drops of hydrofluoric acid. Alternatively, instead of 2 mL of phosphoric acid, 1 mL of hydrofluoric acid can be used. In this case, when the reaction ceases and the solution is cold, 10 mL of boric acid must be added.

Analyte preconcentration and separation techniques may be used successfully for test sample solutions with low analyte and or high matrix concentrations. Solvent extraction procedures are a particularly attractive separation technique. A popular extraction system uses chelation by ammonium pyrrolidine dithiocarbamate followed by extraction into 4 methyl-pentan-2-one (methyl isobutyl ketone). However, sample solutions resulting from extraction often have a small volume and a high salt content. Procedures such as ion exchange
or coprecipitation may also be used for preconcentration. Off-line manual preconcentration is time-consuming and subject to contamination or analyte losses. On-line procedures using flow techniques work reliably, with a significant reduction of time and reagent consumption and with a greatly reduced risk of contamination. Of course, all analyte preconcentration and separation requires complete dissolution of the analyte in the test sample solution and its conversion into a well-defined oxidation state.

A special case of analyte separation is the conversion into a gaseous compound. The best-known example of this technique is hydride generation. Hydride generation can only be applied for selected elements such as antimony, arsenic, bismuth, selenium, tellurium and tin.

Mercury can be easily reduced to the metal which can be volatilized from the solution by a flow of air or inert gas (cold vapor technique).

Whenever an iron and steel sample is treated in order to obtain a test sample solution, there is a potential risk that analyte is introduced through the use of reagents, vessels and from the surrounding air. As for the grade of the reagents, the nature of the impurities may or may not be important, depending on how the reagent is to be used. If the acid is to be used to digest a sample for the determination of trace metals, the presence of metallic impurities in the acid may have a significant effect on the results. For this application, high-purity, metal-free acids are required. Significant contamination can be caused by elements that occur in high concentrations in the environment (e.g. aluminum, calcium, iron, silicon, sodium or zinc). Contamination by laboratory vessels, tools, reagents and loss of the analyte by sorption or volatilization, must be avoided during test sample solution preparation. When needed, ultrapure reagents should be used in conjunction with 18–25 MΩ cm deionized water. Both new and used laboratory vessels must be scrupulously cleaned before use, especially for work at trace levels.

In order to detect unintended analyte introduction and to minimize the resulting errors, it is essential to prepare blank solutions for each batch of samples.

The reagent blank solution must contain all reagents that were used to prepare the test sample solution, in the same concentration as in the test sample solution. If the test portion is subject to an acid digestion, a fusion or any other pretreatment, such as a preconcentration or a separation step, the reagent blank solution should be treated in the same way.

Random contamination usually manifests itself by very large relative fluctuations between replicate blanks.

Contamination may be minimized by decreasing handling through automation, using a separate set of labware for each type of test samples and each type of determination, and or by working in closed systems.

5 SPECTROMETRIC MEASUREMENT PROCESS

Ideally, one would like instruments to produce a noise-free response linearly related to the amount of determinand. In practice, optimization of the signal usually requires both instrumental adjustment and sample modification, either through classical methods of separation (i.e. the removal of interferent elements, and/or the preconcentration of analytes), the addition of matrix modifiers, or buffers, or releasing agents, or the use of matrix-matched reference solutions in order to eliminate or minimize interferences.

After having chosen the wavelength recommended by the instrument manufacturer or by the literature, a preliminary analysis has to be carried out in order to detect the presence of interferences and to evaluate how to avoid them.

The approach for avoiding interferences depends on the nature of the analyte and on the matrix (low-alloy steel, stainless steels, etc.). Optimization of the instrument will be carried out during the determination procedure according to the pertinent guides.

5.1 Interferences

Interferences are generally classified into spectral and nonspectral interferences. Interferences can be specific for a particular analyte or be nonspecific. Their influence on the analytical signal can be additive (causing a parallel shift of the analytical function) or multiplicative (changing the slope of the analytical function).

Spectral interference is a general term used to cover various forms of overlapping of lines from the matrix and the concomitant elements with the analytical line of the analyte element. This overlapping can take the following forms:

- direct coincidence of lines
- overlapping of very close lying lines
- overlapping of broadened lines
- continuum radiation.

Nonspectral interferences are due to a change in the number of free atoms of the analyte element. They are classified according to the place or stage at which the particular interference occurs (transport, solute volatilization, vapor phase-dissociation, ionization-, spatial distribution). Nonspectral interferences may often be recognized by an underproportional reduction of the measured value upon dilution or by an incomplete or too high recovery of added analyte.

Every spectral interference can adversely influence both the precision and the accuracy of the determination.
Once the presence of spectral interferences has been recognized, an attempt should always be made to see whether the analyte element can be determined free of interferences at another line.

When a matrix effect is present, measures to be taken to remove the interference or to correct for it are a function of the technique used.

In FAAS one or more of the following measures should be taken:

- Use of a flame with a higher temperature and higher reducing power, such as the nitrous oxide/acetylene flame, in which molecular components are more completely dissociated.
- Addition of a spectrochemical buffer in order to enhance the formation of analyte atoms.
- Use of matrix-matching or the method of additions if the interference is nonspecific.
- Separation of the analyte element and interfering concomitants by extraction, precipitation, etc.

In GFAAS matrix effects can be minimized by the

- addition of an appropriate chemical modifier;
- optimization of the temperature program;
- atomization from the L'vov platform;
- use of a more powerful background correction system such as the Zeeman correction effect, instead of continuum source background correction;
- separation of the analyte element and interfering concomitants by extraction, precipitation, etc.;
- use of the method of additions when nonspectral interferences are present.

Loss of As, Se, Te during ashing of the sample can be reduced by the addition of nickel ions to form nickel arsenide and this type of compound.

Cd normally lost at 500 °C can be stabilized by 2% ammonium phosphate up to 1000 °C. Such modification not only reduces losses on ashing, but also permits the use of higher ashing temperature and thus may allow background and other matrix effects to be minimized.

In AES an appropriate choice of spectral lines is necessary in order to avoid line coincidence. Limitations arise from the spectral range of the instrument and from mechanical constraints such as the minimum distance between two exit slits. Compromises are required which often preclude the use of the best line. Typical line coincidence problems are encountered in steel analysis by AES with the following lines: B 249.68 W 249.66, Al 396.15 Mo 396.15, Ti 334.94 Cr 334.93, Mn 257.61 W 257.62, Cu 324.75 Mo 324.76, Pb 220.35 Ni 220.35 Co 220.34 W 220.38. Only one line of P (178.28 nm) is free from interferences in the presence of Fe.

An exact knowledge of the radiation background and of the emission lines of concomitants in the neighborhood of the analytical line is essential to achieve satisfactory correction and accurate results. A means to detect interferences is to compare the spectrum of the pure analyte in acid solution with the spectrum of the analyte in the sample solution and then scanning across a short region (0.1–0.2 nm) of the spectrum in the vicinity of a proposed analyte line. Efficient and accurate correction for these interferences normally requires a means of measurement of the background intensity adjacent to the analyte wavelength, preferably on both sides as well as a means of applying previously determined correction factors to compensate for line overlap interferences.

The internal standard technique is often used in steel analysis when simultaneous instruments are used. In this approach an element that does not occur in measurable quantities in the sample is added in precisely the same amount to all blanks, standard and sample solutions. In many cases yttrium or scandium will meet these requirements. The emission intensity of the internal standard element is measured at its own emission line at the same time and in the same way as that of the analyte. Each element channel's signal is divided by the signal of the reference element before further calculation takes place.

5.2 Calibration

Calibration can be carried out according to three techniques: the standard calibration technique with or without matrix-matching, the bracketing technique and the method of additions.

In the standard calibration technique, calibration solutions with equally spaced analyte concentrations that span the desired working range have to be prepared. The number of these solutions is linked to the technique and to the desired uncertainty. Generally in AAS five solutions must be prepared, where one is the blank value. In AES, due to its wide linearity range, calibration is possible even with a single sample, with a suitable blank.

In the bracketing technique, calibration solutions just below and just above the analyte concentration of the test sample solution are used.

In the method of additions the approximate concentration level of the test sample solution must be known in order to establish the analyte addition volumes that must be used. The concentration of the test sample solution with the highest addition must still fall within the linear range. The method of additions cannot be used when spectral interferences are present.

Generally, in iron and steel analysis, when the standard calibration or bracketing technique is used, the main constituents of the matrix (iron, in the case of nonalloyed
6 QUALITY ASSURANCE CRITERIA

In iron and steel analysis, as in many other fields, the use of validated methods as well as traceability calibration have become a subject of increasing and fundamental significance.

“Validated methods” means that the required tolerance of all measurements undertaken within the method (volume, temperatures, masses), the forms of the determined measured, including speciation, and the effect of the interferences, have been widely investigated and quantified under realistic conditions, significant sources of error have been singled out and adequate means of controlling them have been identified.

Several approaches may be used to validate methodology. When reference samples are available that are similar in all respects to the test samples, the process is very simple. It consists of analyzing a sufficient number of reference sample and comparing the results to the expected or certified values. The use of appropriate reference materials can also enable analysts to demonstrate the accuracy of the results, calibrate equipment and methods, monitor laboratory performance and enable comparison of methods by their use as transfer standards.

When suitable reference material is not available, several other approaches can be used. For example it is possible to compare the results of the method to be validated against those obtained from the same sample using other validated methods. (When using validated methods it is necessary to have a complete understanding of them before working through them for the first time. This will ensure the greatest degree of reliability from them and will allow one to compare the results obtained from one method against those obtained by another method based on completely different physico-chemical principles.)

One possible tool of validation is the use of spiked samples. Spiking does not necessarily have to be restricted to the given analyte. Spiking may include anything added to the sample in order to gauge the effect of the addition. The sample could be spiked with varying amounts of a particular interferent, for example, with the aim of establishing at what concentration of interferent the determination of the analyte is adversely affected. The splitting of the sample gives an idea of the variation in the operational condition which can be expected during routine use of the method.

Validation can also be carried out through collaborative tests (interlaboratory study, proficiency testing schemes, certification exercises etc.). Collaborative tests can identify systematic errors.

Measurement on analogous reference materials provides a further validation tool. Even if an exact match between reference material and sample cannot be obtained, the use of the closest match available is better than nothing. It is important to take the reference material through the whole analytical procedure. This will provide a true reflection of the capability of the method and the equipment.

Many Certified Reference Materials (CRMs) are available for iron and steel analysis. Included among steel CRM producers are NIST (National Institute of Standards and Technology), BAM (Bundesanstalt fuer Materialforschung und Prufung), IRSID (Institute de Recherche de la Siderurgie), BS (Brammer Standard Company), BAS (Bureau of Analyzed Samples), CTIF (Centre Technique des Industries de la Fonderie), JK (Jerkontoret), JSS (The Iron and Steel Institute of Japan) and others. BAM, BAS, CTIF, IRSID and JK are members of a producers’ group founded for the production of CRM in the iron and steel industry, originally responsible to the European Community for Coal and Steel. Today this group is acting on behalf of the European Committee for Iron and Steel Standardization (ECISS). The finished samples are sold under the name EURONORM CRM.

As concerns traceability, much has been written and many standardizing bodies are working to more clearly define the scientific and statistical requirements for achieving measurement traceability. However, a clear definition of the scientific and statistical requirements for achieving measurement traceability in iron and steel analysis is missing too.

Therefore, in the framework of ISO (ISO TC 17 SCI) an “ad hoc” group has been set up in order to study the traceability of steel analysis from SI units to routine determinations. The group would investigate documents concerning existing CRM, compare certified values and those from SCI tests, draft requirements for methods and CRMs and ultimately publish a guideline document.

7 STANDARD METHODS OF ANALYSIS

Many standard reference methods for steel analysis are solution-based AAS and AES methods.

Such methods are studied and set up on a collaborative basis, in the framework of international, European and national committees for standardization, such as ISO, Comité Européen de Normalisation (CEN), American Society for Testing Materials (ASTM), Association Francais de normalisation (AFNOR), British Standards Institution (BSI), etc. The standards are optimized to give the highest possible accuracy (precision and trueness), which means that the procedures, in many cases, differ from those normally used in routine analysis.

Such standard methods are evaluated by means of experiments in which a number of laboratories take part. The standardization experiment is designed to reveal and solve any technical problems and to estimate the characteristics of the analytical method. After this stage a precision experiment follows. The aim of this exercise is to establish a concentration range, as well as repeatability and reproducibility values for the method.

Reference standard methods are used to establish element concentrations for CRM and to resolve disputes or doubts when methods, analysts, or laboratories produce disparate results.

Table 3 lists the standard methods published by ISO for the determination of elements in iron and steels.

Automation of Analytical Control in the Steel and Metals Industry

Jean Petin
Mondorf, Luxembourg

1 Introduction

Analysis for production control in the steel and metals industry is performed on solid samples. The two main techniques used are optical emission spectrometry (OES) and X-ray fluorescence (XRF). In both techniques the surface of metallic samples is prepared by taking off the surface layer, and oxidic and mineral samples are prepared as beads either by compression or fusion of a powder. For ancillary techniques small pieces of metallic samples are cut off and weighed before analysis.

In this paper automation is defined as the replacement of operators by automatic devices. The genesis and the functions of automatic systems in the production control laboratories of the steel and metals industry are described.

1 INTRODUCTION

Analysis for production control in the steel and metals industry is performed on solid samples. The two main techniques used are optical emission spectrometry (OES) and X-ray fluorescence (XRF). In both techniques the surface of metallic samples is prepared by taking off the surface layer, and oxidic and mineral samples are prepared as beads either by compression or fusion of a powder. For ancillary techniques small pieces of metallic samples are cut off and weighed before analysis.

Each piece of equipment performing one of these preparation or analysis steps can be considered as a workstation performing its task in a self-contained manner. Such autonomous stations have been developed progressively along with the development of computer technology. Microprocessors became part of the instruments to perform calculations and to control sample introduction, for example via a turntable, whilst sample preparation equipment was equipped with programmable logic controllers (PLCs) to monitor the operation. These were the starting points of automation.

In this paper automation is defined as the replacement of operators by automatic devices. An automated laboratory consists of fully autonomous workstations, a sample transfer system between these stations and the necessary software to control the set-up.

Automation of tasks in analytical chemical laboratories started in the early 1980s using small, human-scale robots to perform repetitive analysis mainly in the pharmaceutical and biochemical industry.

The development started in the USA and was promoted by manufacturers proposing tools and concepts to the user community. Such systems could be installed on benches where the workstations were arranged around a robotized sample transfer system.

The development of laboratory automation for production control in the steel industry started at the same time in Europe, but it was initiated by the user. In view of the size of the equipment and the nature of the environment, the tools used were different from those used in the above-mentioned fields.

As will be seen later these tools had to be, at least in part, developed in response to and in association with the first users.

To some extent equipment and concepts used in the cement industry could be adapted to analytical control in the steel industry. The cement industry was the first to introduce fully automatic laboratories integrating sample taking, preparation and analysis. Cement manufacturing is a continuous process with samples being collected at short intervals, for example every 15 min, averaged and prepared for analysis every 2, 4 or 8 h. An aliquot of the average sample is ground to a given particle size, pressed into a pellet and analysed by XRF. This procedure could be adapted to the analysis of slags and sinters in the steel industry. In a minority of cases the sample is a fused bead, that is, the sample is mixed with a flux, usually a borate, and melted in a platinum crucible to form a glass. The melt is solidified on a platinum dish producing a fused bead. As mineralogical and grain-size effects are suppressed in the fused bead, the analytical results obtained are more accurate, but the technology to be automated is far more complex.

In this paper automation is defined as the replacement of operators by automatic devices. The genesis and the functions of automatic systems in the production control laboratories of the steel and metals industry are described.
The technology used for the analysis of powdered material in the cement industry was adapted for the analysis of oxidic materials such as ores, slags or sinter in the steel industry by adding where necessary an additional step to crush the sample and take out any metallic particles before the final grinding.

In controlling the steel-making process, however, the primary task is the rapid analysis of pig iron and steel samples taken from the melt. The main analytical technique used for this purpose is spark ablation OES. This technique not only permits analysis for metallic constituents but can also be used for the determination of carbon, sulfur and phosphorus in steel. It has also been possible to detect nitrogen and even oxygen by OES since the early 1990s. Automation of OES is more difficult, as the operator must evaluate the quality of the sample before the analysis and also the quality of the burn produced by the spark discharge process, therefore some objective criteria have to replace the judgement of the operator on the quality of the sample.

As will be seen later, these problems had already been solved with the implementation of the first systems and this had largely contributed to the rapid acceptance of the technology. The nonferrous metallurgical industries such as those dealing with Al-, Cu-, or Zn-based materials have rapidly accepted the concepts developed for steel. The only change made was to the method of preparation of metallic samples. Steel samples are relatively hard and the abrasion techniques used for the preparation of the sample surface are not applicable to the softer nonferrous samples.

2 HISTORY OF AUTOMATION

2.1 The Cockerill Approach

Although some attempts to automate steps of the analysis in steel plants had been made before, the automation project undertaken in the Montignies steel plant of the Belgian steel company Cockerill-Sambre can be considered to be the first successful project to integrate the automation of sample transport, sample preparation and analysis by OES and XRF spectrometry of steel, pig iron and converter slag samples. This was complemented by manually operated C, S and N analyzers.

Planning started in 1982 in response to pressure from the metallurgists asking for a quicker analytical output in order to cope with the requirements for the analytical control of the LD basic oxygen converter steelmaking process.

A new laboratory situated at ground level 8 m beneath the converter floor was installed in a two-storey portable cabin. At the ground floor of this cabin the automated area included the arrival point of the sample transport tubes, a preparation machine for metallic samples, a preparation machine for slags, an X-ray spectrometer, an optical emission spectrometer and an image analyzer for the inspection of steel samples. All this equipment was arranged around an industrial robot (Figure 1). In addition a carbon–sulfur analyzer, a nitrogen analyzer and a glow discharge optical emission spectrometer were installed in the manually operating part of the ground floor. On the first floor of the cabin, ancillary equipment such as the computers, the air conditioning equipment and facilities for the operators were installed.

Samples are identified on industrial computer terminals by the steelworks operatives before dispatching to the laboratory. Samples are transported either by gravity or by pneumatic tubes. Metallic samples which are transported pneumatically travel in a so-called open cartridge. The sample is gripped in a holder ahead of a pusher which strikes a ring at the arrival point causing the sample to be released and fall under gravity into a storage tube. Samples transported by gravity arrive directly in the storage tube. There is a separate arrival tube for each type of sample: steel samples from converters, ladle or continuous casting plant; iron samples from the mixer; desulfurization or blast furnace slags. Two computer controlled valves trigger the release one by one of the samples according to the fixed priorities.

The released sample falls onto a belt which is immersed in cooling water before it is automatically introduced into the preparation equipment. The sample is a so-called double medal lollipop sample (Figure 2). In the preparation machine the pin is first cut off by a disk and the thinner part is also removed for the determination of C, S and N. The surfaces of the main sample are then ground on an abrasive band in a manner such as to avoid
AUTOMATION OF ANALYTICAL CONTROL IN THE STEEL AND METALS INDUSTRY

Figure 2 Samples used for liquid steel control. (Reproduced by permission of Soled Industries.)

excessive sample heating. After preparation the sample is taken up by the robot and transferred for inspection to the camera of the image analyzer. Defects are seen by the camera as different shades of gray and the computer determines the location suitable for a maximum of four good sparking areas.

The sample is then transferred by the robot to the spark stand of the OES spectrometer and positioned for spark discharge exposure on one of the predefined sound areas. A minimum of two spark discharges are performed and checked for agreement with the predefined deviation tolerance. If outside the limits, two more exposures can be performed in order to find an agreement. In case of failure a new sample is requested. After exposure the sample is stored by the robot.

Pig iron samples are prepared on the same equipment, but are analyzed by X-ray spectrometry.

Slag samples arrive by gravity in the laboratory and are manually introduced into the preparation machine. This machine combines a crushing of the sample followed by a magnetic separation of metallic particles. The sample is then finely ground in a swing mill and pressed in a steel ring with a boric acid substrate. This ring is transported by the robot to the sample turntable of the X-ray spectrometer. After analysis the ring is put into a storing position.

Two operators perform ancillary work such as carbon, sulfur and nitrogen determination, thus completing the analysis of the steel samples. They also carry out background work on batch samples or initiate recalibration of the optical emission spectrometer and may also perform troubleshooting activities. In the case of major failure they will use the OES spectrometer to analyze manually steel and pig iron samples.

The Cockerill project was the origin of the development of the automation of production control laboratories in the steel industry and also led to the implementation of laboratory automation in the nonferrous metals industry.

Up to then only the cement industry was equipped with automatic laboratories using X-ray spectrometers for analyzing samples in the form of pressed powders. The instrument suppliers were not ready for such automation projects in the steel industry; the major part of the necessary hardware and software had to be developed or adapted to the specific requirements in the steel industry.

The main developments necessary for this project were:

- the open cartridge transport system;
- the preparation machine for steel and iron samples;
- the adaptation of an image analyzer used in metallography to the inspection of steel samples before analysis – a special illumination system for the sample and specific software was required;
- design of the gripping tool of the robot;
- in-house modification of the spark stand of the optical emission spectrometer for the automatic sample loading;
- addition of a metallic iron screening module to the slag preparation machine.

All the software was written in-house in macroassembler using a network of PDP 11 computers supplied by DEC®.

With the exception of the general study, the software and the coordination work performed in-house, the cost of the project was estimated at $1 million.

Thanks to the liberal attitude of the Cockerill staff, laboratory managers from all over the world were able to visit the project and convince themselves that automation of a laboratory for production control was feasible.

2.2 The Cabin Laboratory Concept

The project at Cockerill had shown that automation of spectral analysis of steel samples was possible. Since the
supplies market was not prepared for these developments, it meant that the user himself needed to become deeply involved. This was a costly exercise and at the same time it had been shown that automation did not seem to reduce the time of analysis. These considerations generated an alternative approach which took the form of a demonstration project under the aegis of the European Community for Coal and Steel (ECSC) research organization. The project involved collaboration between a steel company ARBED from Luxembourg and a German spectrometer manufacturer. The idea was to bring the analytical facilities as close as possible to the steelmaking process and to install an emission spectrometer and a surfacing machine for the preparation of the steel samples in an air-conditioned enclosure or cabin (Figure 3). The sample was introduced directly by the operator who sampled the melt, from the outside through a small window on to the table of an automatic horizontal surface grinding machine (Figure 4). The transfer between machine and spectrometer was performed by a small robot. This robot also had access to a magazine containing recalibration and control samples, making it possible to run the system in a fully automatic way without an operator being present. A daily maintenance of about 30 min was sufficient to keep the system in good condition. So it became possible to install such a system close to the vessels such as converters, ladles or electric arc furnaces, where a rapid analytical response was required.

Instead of an image analyzer for the control of the quality of the sample, the intensity of an iron spectral line from a single spark discharge was monitored during the first 3 s of the presparking sequence. If the intensity was beyond a preset level, the discharge was interrupted, the sample was moved and a new discharge was initiated. This test is known as SEREPS (self-regulated prespark). Two values had to be within predefined limits before a result was released. Experience showed that the number of bad samples was reduced drastically by the fact that the operator who took the sample was aware of this checking process and was confronted 90 s later with the result.

Even during the testing of the system within ARBED and afterwards by Ovako Steel and British Steel, other spectrometer manufacturers took up the concept and began installing such systems.

The first operational system, called Spectrolux at ARBED Esch-Schifflange works in Luxembourg, was located between two LD-AC converters and its cost was recovered in less than 6 months due merely to the increase in productivity at the steel plant.

British Steel, who had evaluated the prototype developed in the ECSC pilot project and had contributed by specifying the first industrial systems, was the second industrial user of the Spectrolux system.

2.3 Inferences from These Two Approaches

As already mentioned the Cockerill approach, which was a great success, had not only shown the feasibility of automation in this field, but also initiated the development of appropriate or modified equipment by the respective manufacturers. The first follow-up was the cabin concept developed in collaboration between a user and a spectrometer manufacturer. As part of this project a new sample surfacing machine was also developed by the spectrometer manufacturer.

The two main reasons for the development of the cabin system were the higher cost of the Cockerill system and the fact that such automation does not reduce significantly the analysis time.
AUTOMATION OF ANALYTICAL CONTROL IN THE STEEL AND METALS INDUSTRY

It had been later shown that the automation of sample transport significantly increased the costs of the automation. Setting up a cabin very close to the production vessels improved the response time compared to an automated laboratory where transport times were dependent on the distance between existing laboratories and the production site.

It is interesting to note that the two systems took almost equal shares of the market between 1985 and 1999. The choice largely depends on the local conditions. Not only is the distance between production site and laboratory important, but the size of the steel-making plant must be considered also. Large plants where the decentralized cabin approach would multiply the installations generally use a centralized arrangement either in the existing premises or by creating new ones. Sometimes the two schemes are combined by adding a central laboratory to a decentralized unit close to a production device such as a converter or a ladle furnace where the response time is especially critical. In order to reduce costs, sample transport is not always included in the automation and an operator handles the introduction of the samples arriving by pneumatic tube into the analytical lines. This operator also takes care of any troubles that might arise.

Implementing a combined unit of a sample preparation machine and an optical emission spectrometer is fairly simple whether it is installed in a cabin or in a laboratory. Larger systems combining automatic sample transport, several lines using optical emission, and XRF and even automatic ancillary techniques used for carbon, sulfur or nitrogen analysis need careful planning. As manning levels in the steel industry have been significantly reduced, big projects are now entirely subcontracted. The project coordinator is either a separate engineering company or one of the suppliers. In-house developments are nowadays an exception. Nevertheless the customer is well advised to define his needs and organization very carefully and to ensure a close follow-up with the project coordinator, as equipment and software packages are delivered by different suppliers. A preliminary set-up and function test is highly recommended before delivery.

3 HARDWARE

3.1 The Components

3.1.1 Sample Transport to the Laboratory

In a centralized laboratory controlling the different vessels used in steel production, the samples arrive by pneumatic tube. The identity of the sample is registered on a computer terminal installed at the despatch station or deduced from the departure time and the despatch station location. At the automatic receiving station the sample is extracted from the carrier and transferred either by a robot or by a conveyor belt to the sample preparation machine.

In the case of a stage laboratory installed close to the production site there might be a mix of sample transport: by pneumatic carrier, manual transport or sample transport by gravity through a chute if the laboratory is at a lower level under a production unit.

For cost reasons this step is not always automated and an operator dispatches the samples and supervises the sample preparation equipment.

In the case of a cabin laboratory the sample is introduced into the system by an operator through a small opening in the cabin wall.

3.1.2 Metallic Sample Preparation

3.1.2.1 Steel Samples

Steel samples are generally of the lollipop type (Figure 2). In order to perform a spectral analysis the sample must be prepared. This consists of removal of the pin at the end of the sample, the preparation of the sample surface by grinding and optionally removing a small sample for the separate determination of carbon and sulfur or nitrogen. Two different pieces of equipment have been developed for this task. One of these uses one or two narrow vertical grinding belts and may also include the tools to cut off the pin and punch out small pieces for the ancillary determinations. In this case the sample is a so-called double thickness sample with a spectral part having a thickness of 8–12 mm and a tongue having a thickness of only 4 mm. This tongue is punched in order to obtain small pieces each of about 1 g in weight which are used for the separate determination of carbon, sulfur or nitrogen. The second piece of equipment (Figure 4) uses a large horizontal grinding belt and includes a water cooling unit. Removal of the pin and the punching are performed on separate small units. It is important to take off sufficient material, normally a layer of 0.7–1.3 mm, in order to eliminate possible segregation within the sample and to obtain an even surface for the spectral analysis. The sample is positioned at the exit end of the equipment and from here on the preparation process is fully automatic. The same equipment is used to prepare the control and calibration samples of the emission spectrometer. These samples are introduced from the exit end as only a final grinding is necessary and these samples are then stored close to the spectrometer.

3.1.2.2 Nonferrous Metals

Nonferrous metals such as copper alloys, zinc or aluminum are much softer than
steel. In addition hard precipitates, for example dendrites, may be part of the sample. To prepare these soft samples and avoid a smearing effect of the precipitates a milling machine is used. Two different tools can be used for a preliminary coarse milling followed by a final fine milling. These pieces of equipment are also fully automatic and adapted to prepare both the control and calibration samples.

3.1.3 Oxide Sample Preparation

3.1.3.1 Pellet Preparation Oxide material is sampled from the process (sinter belt, blast furnace or steelmaking unit) and a small aliquot of about 100 g is sent to the laboratory. The automated preparation units are derived from those used in the cement industry which comprise a swing mill and an automatic press (Figure 5).

For their use in the steel industry an optional jaw crusher performs a coarse crushing and a magnetic separator eliminates any metallic particles included in the sample. Part of the automatic function is a cleaning cycle with compressed air and aspiration of the removed particles. Sometimes the vessel and the rings of the swing mill are cleaned with an organic solvent such as isopropyl alcohol. The final pellet may include a binder or be pressed into a steel ring to prevent partial crumbling during manipulation.

3.1.3.2 Bead Preparation In order to eliminate mineralogical and grain size effects, some users find it necessary to prepare a fused bead, that is, the sample is fused with a borate such as lithium tetraborate in order to obtain a glass in the form of a disk. This fusion is generally performed in a crucible made of a platinum–gold alloy (95–5%) heated to a temperature of about 1150°C. In automatic systems heating is performed using either induction heating or gas burners. Such a system includes the automation of the weighing operations and of crucible cleaning (Figure 6).22–24

3.1.4 Analysis by Optical Emission Spectrometry

As has already been shown in the section on the history of automation, steel and iron samples are normally analyzed by spark emission spectrometry. The hardware of the spectrometer used differs from a manual spectrometer only in respect of the addition of an automatic sample clamping unit to the spark stand as well as an automatic electrode cleaning device (Figure 7). Other differences are part of the software. A spectrometer control and recalibration strategy must be established and generally control samples are analysed at preset intervals. If the result is outside preset limits, a recalibration procedure is automatically initiated. In addition a so-called type calibration can be used for steel qualities with very narrow specifications. In such a case a type sample of similar composition to the unknown sample is analysed shortly before calibration and the two results are automatically matched. As we have seen the most difficult task to automate is the evaluation of the quality of the sample. Since the use of an image analyzer first developed by Cockerill is a rather expensive approach, alternative methods have been used. The simplest is the calculation of the standard deviation between several spark exposures on the same sample in comparison with preset limits. If the results of two exposures lie within these limits, the average is transmitted automatically to the production monitoring computer. If not, a maximum of four exposures are performed in order to find two consistent values,
AUTOMATION OF ANALYTICAL CONTROL IN THE STEEL AND METALS INDUSTRY

otherwise the sample is rejected. Another test called SEREPS was developed as part of the cabin concept and combined with the previous method. As these latter tests are performed during the sparking process, samples with cracks or holes containing water introduced during the cooling operation are not detected and the water contaminates the spark stand. Human intervention for cleaning and drying therefore becomes necessary; weighing the sample before analysis reduces this risk.

3.1.5 Analysis by X-ray Fluorescence

Wavelength dispersive XRF is known to be a well established measurement technique giving very reliable results from the parts per million range to 100%. It is the preferred control method in any industry using minerals, and sample changers for this purpose had already been developed in the 1970s. An X-ray spectrometer with a sample changer is a self-contained workstation where only the software has to be adapted to include the station in an automated laboratory.

3.1.6 Ancillary Techniques

Ancillary techniques such as the determination of carbon and sulfur by combustion or nitrogen by carrier gas extraction in many laboratories are not completely automated, despite the fact that the analyzers can be considered as autonomous workstations. The reason for this situation is the fact that automation of central laboratories has reduced the manning levels but not completely dispensed with all the staff. Some examples of such automation, however, do exist. Sample handling is performed by adding a human-scale robot to the equipment and bringing a 1-g sample portion to the working area via a small tube using compressed air for the transfer.

3.2 Sample Handling

3.2.1 Sample Transfer between Workstations

Although Cockerill used a large industrial robot for its automation project, conveyor belts or chains combined with manipulators or human-scale robots were widely used in some of the follow-up projects (Figure 8). The main reason for this change was the cost of adapting the existing housing conditions. Transporting a sample with a belt or moving a sample on a slideway may result in inaccurate positioning or a sample may be blocked by going sideways.

As an automated system is only as good as its weakest link, it is of paramount importance to avoid such uncertainties. Whenever possible only “pick and place” movements should be used. The cabin approach previously described employed this concept, as did the Cockerill system except for the cooling step on arrival of the hot sample where a conveyor belt is used to transfer the metallic sample to the surfacing machine. Recently two companies have developed systems where a gripping device is mounted on a digitally indexed track. One uses a manipulator and the other uses a revolutionary double track based robotics system simultaneously operating two human-scale robots, one being placed upside down.

Figure 7 View of a spectrometer sample stand with automatic clamping and cleaning devices. (Reproduced by permission of ARL.)

Figure 8 View of a conventional automated laboratory. (Reproduced by permission of Philips Analytical.)
Anticollision software prevents the robots from colliding. The workstations are placed along the two sides of the track. For each transfer the nearest one is activated in order to optimize the speed of operation. This new arrangement is totally “pick and place” and has the same access facilities as a conveyor belt or chain.

3.2.2 Sample Identification

There are two aspects to sample identification. The sample must be identified in order for the system to choose the appropriate analytical program and the correct transmission pattern. In addition it may be necessary to physically identify the sample for storage and control purposes.

Sample identification may be done via identification terminals at the despatch stations of the automatic pneumatic system or on introduction into the cabin. For a cabin set-up the task of the operator may be reduced to simply identifying the vessel where the sample originated and the process computer of the steel plant then adds the details of the identification. It may also be deduced by the system from a specific despatch line and time.

If the sample transport is not automated, the operator at the arrival station has to identify the sample for the system and also has the option of putting an identification label on the sample. In automated systems physical identification has always been a problem. The early systems avoided automatic identification by manually labeling the samples after analysis based on their position on a storage rack. The first automatic labeling stations used ink-jet systems which were subject to troubles and malfunction. A much safer technique is the use of paper label dispensers. These labels provide an identification in clear print and by bar code.

4 SOFTWARE

4.1 Sample Tracking Software

The identity of each sample includes a code defining the sample preparation scheme and equipment, instruments used for analysis, the analytical scheme and criteria for result merging and transmission.
A supervising program coordinates the priorities and the different tasks to be performed. Due to historical reasons and the relatively small size of the market, the two principal suppliers of automatic sample transport systems are also suppliers of sample preparation equipment. They deliver with their package a sample tracking system covering the transport scheme, the sample preparation scheme and the sample priority and delivery scheme to the different analytical stations. Every workstation is either equipped with a PLC or a personal computer running the instrument specific software. Results coming from the different instruments are transmitted to a result managing program or to a laboratory information and management system (LIMS) which organizes the result merging, quality assurance and transmission to the final users. As a result of this complex arrangement supervising programs are at least partly customer specific and must be carefully tested before final installation. Most supervising programs include a synoptic chart showing in real-time the location and progress of the different samples. In the case of a cabin system containing only sample preparation equipment and an emission spectrometer the organizational functions are greatly simplified. Modern emission spectrometers are able to determine carbon and nitrogen with sufficient accuracy and precision to satisfy the requirements of an increasing number of process control situations in the steel industry.

4.2 Software for Instrument Calibration and Quality Assurance

The basis for the software is the package developed for manually operated spectrometers. These programs must be augmented by routines and algorithms permitting an automatic release of the results which satisfy predetermined conditions. For emission spectrometry this includes an evaluation of the quality of the burn, as has been explained previously in this text. Emission spectrometry and XRF are comparative methods. The instruments are delivered precalibrated or are calibrated on-site on delivery to suit the requirements of the user. Samples of known composition are analyzed and the calibration curves or algorithms as well as interelement or spectral interferences are stored in the computer associated with the instrument.

In order to check and maintain the calibration, control and recalibration samples are analyzed using a predefined strategy. If the results on control samples fall outside the predefined limits, a recalibration procedure is initiated. Generally a two-point calibration, checking the high point and the low point of the curve, is used. The results on these samples are used to calculate correction factors in order to revert to the original calibration. In a robotic system the calibration strategy has to be carefully planned and must take into account both continuous drifts and sudden changes which might occur especially with emission spectrometers. In order to record the quality of the instrument calibration and of the analytical results produced, all data on control and calibration samples are stored and statistically evaluated. It has been shown\(^\text{(29)}\) that for an XRF spectrometer it is possible to implement a statistical process control routine by analyzing a control sample at regular intervals and displaying the results on a chart. Predefined criteria detect deviation trends and automatically initiate a recalibration taking into account not only deviations from the reference values but also trends.

5 PROBLEMS AND BENEFITS

5.1 Maintenance and Troubleshooting

In order to reduce downtimes a preventive maintenance scheme should be put in place. The impact of a failure can be reduced by doubling the number of instruments, maintaining older manual systems in operation or by implementing procedures for rapidly replacing failed components in the system. As the technology has advanced availability times of 99% or better are possible today.

Recently installed systems have a computer link to the manufacturer and distance diagnostics can reduce downtimes or even eliminate them by detecting possible problems before failure occurs.

5.2 Economic Aspects

Justification for automation was at first based on the prospect of reduced manning in the laboratories. Such considerations were often biased by the fact that during the prosperous years staff levels had not been optimized often for social reasons. Today it is recognized that the main justification comprises:

- the reduction of analysis time by locating the analytical facilities as close as possible to the production lines;
- the improvement of the quality of the results by eliminating the human factor;
- the social reform of replacing the monotonous and stressful operator tasks by a smaller number of jobs for higher qualified operators to supervise and maintain these high-tech installations.

6 OUTLOOK

Automation of the analytical equipment used for process control is today a well established procedure. Complete
systems as well as modular components are commercially obtainable and have been proven to be reliable with an availability close to 99%. Careful planning is necessary to define the needs of the process control function and to avoid backlogs of samples. This can be facilitated by the use of an appropriate software package. For complex systems which integrate equipment and software from different manufacturers it is recommended that the services of a specialist company should be used and that a preinstallation test of the system should be included in the planning.

It has been shown recently that the use of laser induced breakdown spectroscopy, where a high intensity laser beam vaporizes the material and excites the vapor to produce a plasma which is analyzed by an emission spectrometer, permits the analysis of conductive and nonconductive material. Early versions of the system have been used to monitor pig iron production in blast furnaces using lollipop samples without the need to prepare the surface of the sample and also to determine the slag composition on vitreous samples obtained by controlled cooling of the liquid slag. Figure 10 shows such a system in its robotic form. For such a configuration sample preparation equipment is no longer necessary and equipment can be installed close to the furnace without the need for any specific operators. A furnace operator simply identifies the sample to the system and transfers it to the entry area where it is picked up by the robot.

Research on in situ analysis of liquid steel has up to now found only the occasional application in process control, but much research effort has been expended in the last 25 years and recently initial trials in secondary steelmaking appear to be quite promising.

**ACKNOWLEDGMENTS**

I would have been unable to write this paper without the help and the updated information provided by my fellow steel chemists A. Daniels, Jean-Claude Hoet, Fernand Hoffert, Ray Jowitt, Patrick Kicq, Masao Saeki, Bernd-Joseph Schlothman and Gotthard Staats and by the manufacturers’ representatives Pierre Brugnago, Volker Dreisbach, Colin Gamage, Reinhard Kamphoff and Huub Smit. The careful correction of the text by my friend Rhys Jenkins not only filled certain gaps in my English, but also included a critical assessment of the contents of the paper.

The iron ore industry is an important segment of the world economy. The main mineral oxides are magnetite and hematite. The composition of iron ore plays an important
role in both the iron (blast furnace) and steelmaking operations. Sampling is done both at the source and at the destination. Sampling protocols and preparation are described. The determination of iron, phosphorus, silica and manganese by methods such as gravimetric (Si) and volumetric (P and Mn) have been replaced by more rapid photometric or flame atomic absorption spectrometry (FAAS) methods. Instrumental methods such as combustion high-frequency furnace infrared (IR) (for C and S) FAAS and graphite furnace electrothermal methods, X-ray fluorescence (XRF) and inductively coupled plasma (ICP) spectrometric methods are used to determine analytes for routine process control. These methods are illustrated in the article. Rapid methods for chemical analysis and quality control, developed by the author, could also be cost effective.

1 INTRODUCTION

The iron ore industry is an important segment of the world economy. It includes natural lump ores and those ores which are processed to enhance the iron content of the products, which may be concentrates, pellets or direct reduced iron (DRI) for use in the iron and steel industry. In 1989 some 50 countries produced 982 million metric tons of iron ore. The world iron ore trade in 1989 amounted to about 423 million metric tons valued at about 11 billion US dollars. Brazil and Australia share the major portion of this trade. Canada, India and South Africa also significantly contribute to the export of iron ore.

The main mineral oxides are magnetite (Fe₃O₄ with Fe 72.4%), hematite (Fe₂O₃ with Fe 69.9%) and ilmenite (FeTiO₃ corresponding to Fe 36.8% and Ti 31.6%). Iron also occurs in the minerals such as carbonate (siderite) and sulfide (pyrite form FeS₂, with Fe 46.6% and S 53.4%) and various and sometimes complex iron silicates. The acceptability and the value of iron ore depend on the ore composition. The main constituent, iron, may vary from 46 to 72%, Si from 0.1 to 12%, Al from 0.1 to 4%. Constituents such as Mn may vary (0.01 to 8%), P from 0.005 to 1.4%, S from 0.001 to 0.9%, V from 0.001 to 0.4%. The composition of the iron ore plays an important role in both iron and steelmaking operations. Some components, from minor to trace elements, are environmentally sensitive. They include Ti, Ca, Mg, Na, K, Ba, V, F, Cu, Pb, Zn, Cr, Ni, Co, Sn, As, Sb, Cd, Bi, Mo, Fe(II), Cl, C, and hygroscopic moisture.

1.1 Sampling and Sample Preparation

Iron ore and iron-bearing feed stock is transported in bulk by ship (special carriers) or rail. The sampling is done both at the source and at the destination. Automated mechanical sampling stations with advanced technology are installed by some establishments, for example at Suldhana Bay (South Africa), South Wales (UK) and in Japan. The sampling techniques must provide a homogenous and representative sample of the consignment. After sample preparation (crushing, pulverizing, grinding, sieving etc.) the sample undergoes further steps for the preparation of an analytical sample according to established practice set out by International Standards Organization (ISO), American Society for Testing Materials (ASTM) and European and Japanese standards bodies.

1.2 Analytical Methods

In commercial analysis the determinations most commonly used are iron, phosphorus, silica and manganese. The older, tedious methods such as gravimetric (Si) and volumetric (P and Mn) have been replaced by more rapid photometric or FAAS methods. Reference and standard methods are used for contractual purposes to determine the value of the iron ore consignments including the characterization and composition of iron ore. The iron content as well as the concentration of the other constituents are important for blast furnace and steelmaking processes, such as basic oxygen furnace or electric furnace operations. These considerations necessitate various sampling protocols as well as method/s of analysis, both classical (standard chemical methods) and instrumental. A distinction must be made here in the choice of the method of analysis. Iron is a major element in the iron ore, concentrate, pellet, etc. (50–90% Fe). For contractual purposes this element is usually analyzed by very precise and accurate noninstrumental methods. Instrumental methods such as combustion high-frequency furnace IR (for C and S), FAAS and graphite furnace electrothermal methods, XRF and inductively coupled plasma/atomic emission spectrometry (ICP/AES) methods are used for determining analytes for routine process control. Gravimetric, volumetric, complexometric, photometric, FAAS, ICP/AES and XRF analysis methods are described. In this article rapid methods for chemical analysis, developed by the author, are illustrated that could also be cost effective to provide analytical quality control as well as reference analysis, worth consideration as standard methods, by organizations such as ISO and ASTM.

2 COMPOSITION

Iron ore encompasses rocks, minerals or aggregates of minerals, natural or processed such as concentrates,
pellets, or DRI, from which iron can be produced commercially.

2.1 Principal Ores

Principal ferriferous minerals occurring in iron ore are: red, brown and specular hematite, marlite and maghemite; magnetite; hydrated iron oxides, including goethite, and limonite; iron carbonates including siderite, chalybite, ankerite and other mixed carbonates; roasted iron pyrites or pyrite cinders; ferrites such as calcium ferrite occurring sometimes in natural ores, but mainly in fluxed pellets and sinters.

2.2 Concentration Ranges of Elements of Interest

Iron ore has diverse composition depending on the mineral characteristics of the ore-bearing materials. The main mineral oxides are magnetite (Fe₃O₄; Fe 72.4%), hematite (Fe₂O₃; Fe 69.9%), ilmenite (FeTiO₃; 36.8% Fe and Ti 31.6%). Iron also occurs in the minerals such as carbonate (siderite) and sulfide (pyrite form FeS₂; 46.6% Fe and 53.4% S). Concentration ranges of elements of interest are: Fe: 30–72%; Si: 0.1–10%; Ca: 0.01–10%; Al: 0.1–5%; Ti: 0.01–5%; Mg: 0.01–3%; Mn: 0.01–3%; P: 0.003–2%; S: 0.002–1%; Na and K: each 0.002–1%; V: 0.005–0.5%; Cu, Cr and Ni: each 0.003–0.1%; Pb and Zn: each 0.001–0.5%; Sn: 0.001–0.1%; water-soluble Cl: 0.005–0.1%; hygroscopic H₂O: 0.05–6% and loss on ignition: 0.25–10%; combined H₂O: 0.05–10%; Fe(II): 1–25%.

3 SAMPLING AND SAMPLE PREPARATION

Importance of sampling is well recognized, as an analysis can only be as reliable as the sample on which it is made. Sampling is an important task which involves skill, judgement, reliability and experience. Sampling precedes sample preparation and involves both manual and automated systems for collecting samples (from the wagons as well as from the conveyer belts transferring the shipment from the cargo hold) in a well-designed system of sampling operations. The sampling and sample preparation steps are based on the objectives of the testing; a sampling plan specifies the minimum weights and number of increments required for each step in the procedure. Samples are then collected and a composite sample (subsample) is prepared for physical tests such as tumbler test, crushing strengths and chemical analysis. The subsample is dried, blended, divided, crushed, pulverized and ground, as required by the test method. This is also true for the manual sampling of iron ore, pellets etc.; using a scoop and combining the increments for sample preparation as stated earlier. Test samples for chemical analysis should be dry, weigh about 50 g, and have a maximum particle size to pass a No. 100 (150 µm) sieve.

4 PHYSICAL TESTS

Iron ore pellets, iron ore concentrates and sinter constitute a considerable portion of iron and steelmaking feed for iron and steel production. The physical tests, tumbler test and crushing strength are indicators of abrasion resistance and degradation by impact in the determination of quality problems associated with the production of pellets as well as performance in the blast furnace. Particle size or screen analysis is intended to be used for compliance with the compositional specification for particle size distribution.

4.1 Particle Size or Screen Analysis Test Methods

The sample is passed through a bank of standard sieves by agitation. The selected sieves are nested and a pan is fitted below the bottom sieve. The nested sieves are covered and mechanically agitated for a specified time. The cover and clamp are removed and contents of each sieve are transferred to a tared pan and weighed. The sieve fractions are then calculated.

4.2 Tumbler Test Method

The sample is placed in a tumbler drum (of specified material and design) which is rotated. The tumbled material is then removed and screened to determine the degradation.

4.3 Crushing Strength Test Method

A load is applied to a single pellet at a specified speed of the compressive platen until the pellet is broken. This procedure is repeated on all pellets of the test sample.

5 ANALYTICAL COMPETENCE AND SAFETY ASPECTS

It is expected that the analysis will be carried out in a properly equipped, environmentally clean laboratory, by qualified and trained analysts capable of performing common laboratory practices skillfully and safely. The work place hazardous materials information system should be in place. All chemicals used in the laboratory should have a material safety data sheet available and personnel acquainted with it. The laboratory shall have
STEEL AND RELATED MATERIALS

in house practice of proper waste disposal (including appropriate devices for emissions control) procedures.

The safety aspects are crucial. Recently ISO has promulgated guidelines for their inclusion in standards and that includes test methods. The guidelines particularly refer to harm, hazard, risk, protective measure and safety, defined as freedom from unacceptable risk. It is desirable to have a short description of safety aspects posted in the laboratory.

6 ELEMENTS OF INTEREST AND CHOICE OF METHODS

The choice of method depends on the chemical properties of the element to be determined. The precise iron content as well as the concentration of the other constituents of the iron ore and other iron-bearing feed stocks are crucial for blast furnace and steelmaking processes such as basic oxygen furnace or electric furnace operations. A distinction must be made here in the choice of the method of analysis. Iron is a major element (50 to 90% Fe) in the iron ore, concentrate, pellet, etc. For contractual purposes this element is usually analyzed by very precise and accurate standard (noninstrumental) methods. Standard methods are used to determine the value of the iron ore consignments including the composition of the iron ore consignment. The reader is referred to articles by Lundell, Hoffman and Bright and somewhat more recent by Harrison, and standard methods for analysis of iron ore, from ISO, or national organizations such as ASTM, UK, Europe, Japan, Australia, etc.

Many standards methods have superseded the traditional methods, such as gravimetric and volumetric (used for Si, P and Mn). Faster photometric methods with improved precision and accuracy are now in use and amenable to automation. The latter are generally used for minor elements e.g. P, Mn, Si, Ti and V. Prior to the advent of FAAS the wet chemical methods for determination of Na and K, were very tedious with questionable accuracy. Elements such as Pb and Zn are now preferably determined by FAAS methods, for better sensitivity and relative freedom from interference. FAAS methods are also used to determine elements, such as Ca, Mg, Na, K, P, Cu, Ni, Cr, etc.

7 COMMON INSTRUMENTAL METHODS

The application of photometry and FAAS for analysis of a single element and multielements have already been alluded to. In industry, laboratory systems are common for sequential and simultaneous multi-elemental analysis. ICP/AES spectrometric methods are also being used for determining analytes for routine process control. However the samples need to be solubilized for both FAAS and ICP/AES. This presents constraints as acid dissolution is often not complete. The undissolved residue has to be separated, fused with a flux and combined with the main solution prior to aspiration and nebulization. The salt concentration poses a problem with salt build up and leads to interference. Alternatively, the sample is fused with borax (sodium tetraborate) in a platinum crucible and the melt is dissolved in acid. For elements such as Na and K, hydrofluoric acid treatment is essential to break down refractory silicates using Teflon™ or platinum ware for sample dissolution.

Carbon and sulfur are normally determined instrumentally by high-frequency combustion IR methods. The accuracy is similar to that of gravimetric (carbon) and iodometric (sulfur) methods (see section 11).

XRF methods are used in routine control analysis. The sample is briquetted with a binder or preferably fused. Common fluxes used in the preparation are borax and lithium carbonate. The fused hot melt is poured into a heated platinum dish to form a bead for subsequent measurement on an X-ray spectrometer equipped with suitable analyzing crystals and detectors.

Apparatus, laboratory ware, deionized (distilled) water and reagent purity should meet the specifications, outlined in national and international standards.

8 TEST SAMPLE WEIGHING PROCEDURE FOR CHEMICAL ANALYSIS

Iron ore is hygroscopic. The analysis is made on a dried sample basis and corrected if required on an as-received basis. The following procedure is recommended in all test methods where a weighed sample is used for chemical (solution) analysis. Transfer the analytical test sample to a weighing bottle. After drying in an electric oven at 100–105 °C for 1 h, cap the bottle and cool in a desiccator for 30 min. Momentarily release the cap to equalize pressure and weigh the capped bottle to the nearest 0.0002 g. Transfer the sample into a beaker or crucible for acid/fusion decomposition and reweigh the capped bottle to the nearest 0.0002 g. The difference of the two weights is the weight of the sample used in the test method.

9 DETERMINATION OF HYGROSCOPIC WATER

The importance of moisture content is twofold. Firstly the value is used in converting the iron content of the dried
sample on as-received basis of the cargo or consignment. Secondly samples may readily absorb moisture even waiting for analysis. It is customary to determine moisture in the sample preparation area in large drying ovens. The physical tests are also done on dry samples.

9.1 Moisture Determination

Transfer 2 g (accurately weighed to nearest 0.001 g) sample of the air-dried sample to a tared weighing bottle with stopper. Dry at 100–105 °C in an electric oven for 3–4 h. Stopper the bottle and transfer to a desiccator and cool for 30 min. Upstopper the bottle and weigh as before. Calculate percent moisture: loss in weight (g) divided by the original sample weight (g) and multiplied by 100.

10 DETERMINATION OF LOSS ON IGNITION AND COMBINED WATER

Normally loss in weight on ignition is due to combined water, organic matter and carbon dioxide from any carbonate present. With materials of high iron content (concentrates, prereduced iron) an overall weight gain is expected. It is prudent to determine both combined water and carbon dioxide separately.

10.1 Determination of Combined Water

Gravimetric and/or Karl Fischer titrimetric methods can be used. The combined water is determined in the test sample, usually a 2 g sample weight, by heating in a stream of dry air at a temperature of 1000 °C, in a combustion train with U-tubes for the preabsorption of sulfur on a silver spiral, followed by a pre-weighed U-tube containing magnesium perchlorate (gravimetric) or Karl Fischer reagent (titrimetrically), for determining the evolved water.

Carbon dioxide is determined by transferring the sample to a round-bottomed flask attached to a purification train to capture the sulfur gases and an absorption system containing a pre-weighed bulb with ascarite and magnesium perchlorate. Dilute hydrochloric acid is added via a tap funnel and heated to boiling. After absorption of the evolved carbon dioxide is complete the bulb is re-weighed for difference and percent CO₂ calculated.

11 DETERMINATION OF TOTAL SULFUR

Total sulfur can be determined by a few methods including the rarely used tedious barium sulfate gravimetric method. The most commonly used instrumental method is the combustion–iodate titrimetric method. In brief, the sulfur is converted to SO₂ by combustion in a stream of oxygen (in an induction furnace set-up using iron, tin and copper as accelerator) absorbed in an acidified starch–iodide solution and titrated continuously during the evolution with a standard solution of potassium iodate. The potassium iodate solution is standardized against a similar type of iron ore of known sulfur content, since the percentage sulfur (yield) evolved as SO₂, varies with different iron ore bodies.

12 PROCEDURES FOR TEST SAMPLE DISSOLUTION USING ACID DISSOLUTION OR ALKALI FUSION

The sample has to be dissolved for all methods requiring solution for traditional wet chemical procedures or by physico-chemical methods such as FAAS, direct current ICP/AES or by auto-analyzer procedures designed for such solutions. Sample decomposition procedure depends on the analyte of interest. Acid such as hydrochloric, singly or in combination with other acid/s, is used for sample dissolution. Acid dissolution invariably leaves an insoluble residue. The latter has to be separated by filtration, the residue ignited, silica removed by HF treatment (if required), and fused with a suitable flux and redissolved in the melt to obtain complete sample solution. If a fusion must be made, it might as well be done at the beginning to save time, provided the procedure can tolerate the flux used for fusion. Several test methods, adopted as ISO and ASTM Standards, and schemes,¹⁴,⁵ have been developed by the author, which among others, include sodium peroxide sintering/fusion in a zirconium crucible to yield rapid and complete sample solution amenable for determining several analytes photometrically and by other physicochemical techniques. In an earlier study, a rapid method for decomposing iron ore in a vitreous carbon crucible by fusing with sodium peroxide was reported,⁶ but this crucible is both heavily attacked and lasts only a few fusions, which makes it relatively expensive. A zirconium crucible is much more resistant to attack by sodium peroxide and lasts for dozens of fusions.

13 METHODS FOR THE DETERMINATION OF TOTAL IRON (REDOXIMETRIC TITRATION)

Iron is the most important and valuable element in iron ore. Several methods exist for its determination. The method involving hydrogen sulfide reduction and dichromate oxidation is very tedious. Acid dissolution of iron
ore is incomplete as well as tedious. Bhargava\(^6\) described a rapid sample dissolution method for iron ore matrix and redoximetric titration of iron by conventional stannous chloride–mercuric chloride reduction and titration of ferrous iron with dichromate. Mercuric chloride has to be added to eliminate the interference of excess stannous chloride needed for the reduction of ferric iron. The ISO had been seeking a mercury pollution free method. Metallic silver (as powder) or generated by the reduction of silver nitrate solution with zinc rods, reduces ferric iron to the ferrous state at the acidity used in the dichromate redoximetric titration. An added feature of the silver reductor column is the ease of regeneration of silver after the latter has been exhausted, for repeated further reduction. Thus the silver reductor\(^7\) method was developed to eliminate mercury pollution. The unique characteristic of using reduction by silver is the validation of its freedom from vanadium interference as is the case with other redoximetric methods for iron determination. The method is rapid, yields results with excellent precision and accuracy, avoiding the tedious manipulations of the acid dissolution procedure. The following procedure\(^7\) uses fusion/dissolution with sodium peroxide in a zirconium crucible, providing complete sample solution and is applicable to the determination of several elements in iron ore.

13.1 Fusion/dissolution with Sodium Peroxide in a Zirconium Crucible

Accurately weigh sample (0.3 g), following the test sample weighing procedure in section 8, into a dry 50-mL zirconium crucible. Mix with 2 g of powdered sodium peroxide and fuse over a Meker burner (low heat), swirling the crucible until the melt is cherry red and clear. Remove the crucible from heat and swirl until the melt solidifies on the crucible wall. Cool the crucible somewhat in air and place in a dry 250-mL beaker. Add 10 mL of water to the crucible and cover the beaker with a watch glass. After effervescence ceases, pour the contents of the crucible into the beaker and wash with 15–20 mL of water. Add 10 mL of concentrated HCl via the crucible as well as water rinsings into the beaker. Boil the solution for 3–4 min. Wash the watch glass and the walls of the beaker with water and continue boiling for about 30 s. Cool the solution and dilute to about 60 mL. Reserve this solution for the reduction of ferric iron via silver reductor and/or for other determinations.

13.2 Silver Reductor Total Iron Redoximetric Titration Method\(^7\)

Prepare the silver reductor by placing silver powder 250 µm (125 g), over a lightly packed glass wool in a column 2 cm in diameter and 15 cm length fitted with a stop-cock and a 100-mL reservoir cup. Activate silver in the reductor by passing about 100 mL of 1 N HCl through the column at a rate of 35 mL min\(^{-1}\). Place a 400-mL beaker containing 25 mL of mixed acids (prepared by carefully adding 150 mL of sulfuric and 150 mL of phosphoric acid to 600 mL of water, cooling and diluting to one litre with water) for collecting the eluate. Pass the reserved solution (section 13.1), through the reductor at a rate of 35 mL min\(^{-1}\) (until there is about 1 mL of acid left above the silver). Rinse the beaker 2–3 times with 1 N HCl and pass through the reservoir and the column as before. Add 5–6 drops of 0.3% sodium diphenylaminesulfonate indicator solution. Titrate immediately with standard potassium dichromate solution to a permanent purple end-point. Calculate the iron content by multiplying the titre (mL) by 5.858 and the normality of potassium dichromate, and divided by the sample weight in g. The silver reductor method has been adopted by ISO (ISO 9508)\(^8\) and ASTM (E 1081).\(^9\)

13.3 Titanium(III) Chloride Total Iron Reduction Method

Another method to eliminate mercury pollution involves the incorporation of titanium(III) chloride; however vanadium still interferes and has to be removed. This method also provides the choice of acid decomposition or decomposition by fusion. In the reduction step, most of the ferric iron is reduced in hot 6 M HCl medium with stannous chloride followed by a slight excess of titanium(III) solution. The excess titanium(III) is oxidized in the hot solution with perchloric acid. The solution is rapidly cooled and the reduced iron is titrated with a standard dichromate solution using sodium diphenylaminesulfonate as indicator. The titanium(III) chloride reduction method has also been adopted by ISO (ISO 9507)\(^10\) and ASTM (E 1028).\(^11\)

14 DETERMINATION OF METALLIC IRON IN DIRECT REDUCED IRON BY BROMINE–METHANOL METHOD

The term “metallic iron” means those forms of iron that are not bonded to oxygen nor present as pyrite. The method is particularly significant for metallic iron contents between 15% and 95% in reduced iron ores (DRI). The metallic iron is dissolved by treatment with bromine–methanol solution. The insoluble residue is separated by filtration. In the redoximetric method the iron is reduced to ferrous iron by stannous chloride and subsequently titrated with potassium dichromate solution. An alternative rapid complexometric titration method, developed by the author (unpublished
internal report), for routine control, is described in section 14.3.

14.1 Dissolution of Metallic Iron

Reflux test sample, accurately weighed (0.5 g) at room temperature in a dry 100-mL conical flask, with 50 mL of bromine–methanol solution (5 mL of bromine in 50 mL of methanol) using a magnetic stirrer, for 30 min. Filter immediately through a glass fiber filter under suction and collect the filtrate in a suction filter flask. Wash the filter 5–6 times with methanol (5 mL at a time) until the washings are colorless (free from bromine), then wash a further 3 times with water, to remove methanol. Transfer the solution to a 600-mL beaker, for the redoximetric determination (section 14.2) or to a 200-mL volumetric flask for the rapid compleximetric titration (section 14.3).

14.2 Determination of Metallic Iron by a Redoximetric Procedure

Add 20 mL of dilute (1 + 1) sulfuric acid to the filtrate, heat the solution cautiously until fumes of sulfuric acid appear, then continue heating to strong fuming. Remove from the hotplate, cool and add 10 mL of hydrogen peroxide (30% v/v). Evaporate until sulfuric acid fumes again evolve. Cool and repeat the oxidation with hydrogen peroxide to eliminate bromides and methanol. Add some water, rinsing the walls of the beaker and heat again to fuming. Cool, carefully add about 140 mL of water and 25 mL of concentrated HCl and boil until all salts are redissolved. Carry out the redoximetric determination\(^{\text{90}}\) using tin(II) chloride, mercury(II) chloride, diphenylaminesulfonate indicator and potassium dichromate. Calculate the iron content by multiplying the titre (mL) by 5.585 and the normality of potassium dichromate. Calculate the weight of the blank from pure silica weight and dividing by the sample weight (g).

14.3 Determination of Metallic Iron by a Compleximetric Procedure

Dilute the filtrate in the 200-mL volumetric flask to volume with water. Mix. Pipette 10 mL aliquot into a 400-mL beaker. Add about 50 mL of water and 0.5 g of ammonium persulfate. Boil for a few minutes to expel bromine. Dilute to 150 mL with warm water. Add about 0.1 g of salicylic acid. Titrate the warm solution (at about 40 °C) with 0.05 M ethylene diamine tetra-acetic acid (EDTA). The change at the equivalence point is from light reddish brown to distinct lemon yellow. Calculate the percentage of metallic iron by using the equivalence factor: 1 mL of 0.05 M EDTA is equivalent to 2.7925 mg Fe.

15 DETERMINATION OF SILICON BY GRAVIMETRY

The gravimetric method involves dehydration of silica. The sample is fused with sodium peroxide in a zirconium crucible. The melt is leached with water and dissolved in hydrochloric acid. Silica is separated by double dehydration with perchloric acid. The two precipitates after dehydration are combined, ignited in a weighed platinum crucible and reweighed after the ignition step. The difference in weight gives impure silica. Hydrofluoric acid and a little sulfuric acid are added to remove silicon as volatile silicon tetrafluoride. The ignition step is again repeated and the crucible reweighed. The difference in weight of the last two weighings gives pure silica. A blank determination is carried out simultaneously using the same amount of reagents and the same operations as described. Percent silica is calculated by subtracting the weight of blank from pure silica weight and dividing by sample weight, multiplying by 100. The gravimetric method is rarely used in routine analytical control. The double dehydration procedure is basically used for reference analysis and establishing silica content in reference standard materials. The preferred methods are photometric or XRF, which will be described in later sections.

16 DETERMINATION OF ALUMINUM BY ETHYLENE DIAMINE TETRA-ACETIC ACID-COMPLEXOMETRIC TITRATION

Some background information for the development of this technique is relevant. Older methods for determining aluminum such as the gravimetric aluminum phosphate method are both tedious and somewhat unreliable. Photometric methods, manual\(^{\text{12}}\) and for auto-analyzer system\(^{\text{4,12}}\) for aluminum determination have been reported. The sample is fused in a nickel crucible with sodium peroxide and solubilized with dilute HCl. After dilution, the photometry is carried out by treating an aliquot of the solution with ascorbic acid to reduce the ferric iron. The color complex of aluminum is developed with Chromazurol S in a solution buffered with sodium acetate at pH 5.3. Both synthetic and standard reference materials (SRMs) for iron ore can be used for calibration and subsequent calculation of result. However problems arose because of the unavailability of a consistent quality of Chromazurol S reagent. Earlier the author developed a direct method for the compleximetric determination of aluminum in zinc alloy,\(^{\text{13}}\) which became the basis of devising an alternative method for aluminum by EDTA-compleximetric titration. This method\(^{\text{14}}\) proved
suitable for reference analysis. The method was applied to a wide variety of iron ores with diverse composition giving excellent precision and accuracy. The results of protocol of international round robin tests and statistical evaluation of the developed procedure led to its adoption as an ISO standard (ISO 6830)\(^{15}\) and by the ASTM (E 738).\(^{16}\) In brief, the sample is fused in a zirconium crucible with a mixed flux of sodium carbonate and sodium peroxide. The fused mass is completely soluble in HC1. The R$_2$O$_3$ oxides are then precipitated with sodium peroxide. The fused mass is completely soluble in HC1. Elements such as iron, titanium and zirconium are separated from aluminum by solvent extraction with cupferron and chloroform. After removal of traces of organic matter from the aqueous phase, the solution is titrated with an excess of EDTA, which is back-titrated with standard zinc solution using xylenol orange as a metallochromic indicator. Addition of ammonium fluoride then releases equivalent aluminum EDTA (noteworthy), which is then titrated with zinc solution. Essential details (illustration of solvent extraction separation coupled with complexometric titration) as described in the procedure\(^{14}\) are important.

### 16.1 Procedure

Transfer 0.50 g of sodium carbonate to a dry zirconium crucible. Add 0.10–0.30 g iron ore sample (containing 0.001–0.005 g of aluminum), weighed using the weighing procedure in section 8 to the crucible, followed by 2 g of sodium peroxide. Mix the contents with a dry stainless steel spatula. Follow the fusion and dissolution procedure (section 13.1). Bring the reserved solution to the boil. Add diluted (1 + 1) ammonia solution dropwise to raise the pH to 5. Boil for 1 min and immediately filter through a whatman No. 41 or equivalent filter paper, containing some paper pulp. Reserve the beaker. Wash the paper five times with hot ammonium chloride (1 g ammonium chloride per 100 mL water containing two drops of concentrated ammonia) wash solution. Discard the filtrate. Place the reserved beaker under the filter funnel. Dissolve the hydroxide precipitate by adding 5 mL of hot HC1 dropwise. Wash the filter with nearly boiling diluted (1 + 5) HC1 until the washings are free from iron. Adjust the volume of the filtrate to 50 mL diluted (1 + 5) HC1. Cool to about 10°C.

Transfer the solution to a cold (10°C) 250-mL separating funnel. Use 25 mL of cold water (10°C) for rinsing the beaker into the separating funnel. Add 20 mL of cold freshly prepared and filtered cupferron (6% in cold water at 10°C) solution. Mix slightly. Add 20 mL of chloroform. Shake vigorously for 1 min. Let the layers separate. Draw off the lower organic layer. Add 5 mL of chloroform to the separating funnel to displace the cupferronates on the surface of the aqueous layer. Draw off the organic layer.

### Table 1 Extraction guide, sample weight, volume (mL) of cupferron and chloroform

Carry out further extraction/s with appropriate volumes of cupferron and chloroform (Table 1). Note that for 0.3 g sample weight an additional extraction with cupferron and chloroform is required as specified in Table 1.

Finally add two successive 20 mL portions of chloroform to the aqueous phase, shaking vigorously for 1 min. Let settle and separate. Draw off the organic layer. Wipe the stem of the separating funnel with a filter paper wick. Drain the aqueous phase into a 250-mL beaker, rinsing with 5 mL of diluted (1 + 5) HCl. Boil for a few minutes. Remove from the heat. Add 5 mL of nitric acid and 10 mL of perchloric acid. Cover with a ribbed cover glass. Evaporate nearly to dryness. Remove from heat and add 10 mL of diluted (1 + 1) HCl. Heat to dissolve the salts and then add 50 mL of water and bring to the boil. Filter through a whatman No. 41 paper and wash several times with hot water. Cool. Add an excess of 0.01 M EDTA (25 mL is sufficient) by pipette. Adjust the pH to 4 (using a pH meter) by dropwise addition first of 10% sodium hydroxide solution till the pH reaches 2.5 and then 1% sodium hydroxide solution. Dilute to 100 mL with water. Cover the beaker and bring to the boil. Keep boiling gently for 10 min to permit complete metal-complex formation. Add 15 mL of acetate buffer and seven drops of xylanol orange (0.1 g, made into a paste and diluted with water to 100 mL and stored in an amber-colored bottle) metallochromic indicator. Stir with the magnetic stirrer and titrate with standard 0.01 M zinc (prepared by dissolving 0.6538 g high purity zinc metal in nitric acid, adding about 500 mL of water, pH adjusted to 4, diluted to 1000 mL in a volumetric flask and mixed) solution. The color changes to a persistent (30 s) pink end-point. Add 10 mL of 10% ammonium fluoride solution (prepared freshly each day in a polyethylene beaker). Boil gently for 10 min, cool and titrate the liberated EDTA with standard 0.01 M zinc solution as before. Record the titre (mL). Percent Al is calculated by multiplying titre mL by 0.02698 and dividing by sample weight in g.

### 17 PHOTOMETRIC METHODS

The technique is basically based on Beer–Lambert’s law where the absorbance of the analyte color complex of the...
species formed, is proportional to analyte concentration. However in practice this is not as straightforward in all circumstances. Elaborate separation is sometimes necessary to isolate the analyte species prior to color formation. In this section recently developed photometric methods for As, Mn, P, Si, Ti and V will be described. Many of these methods have been adopted by ASTM and ISO as standards.

17.1 Determination of Manganese by Periodate
The range of the method is from 0.01 to 5.0%. The sample is decomposed by digestion with hydrochloric and nitric acids followed by fuming with perchloric acid to eliminate chlorides. The insoluble residue is removed by filtration, ignited and fused with sodium carbonate and the melt dissolved in the filtrate. The manganese is oxidized to permanganic acid with potassium periodate. After cooling, absorbance is measured at 545 nm. Calibrations are made using manganese standard solution to cover the range with treatment for photometry similar to the sample. For future development the author suggests that the sample could be decomposed by sodium peroxide fusion and the water-leached melt dissolved in perchloric acid; then proceed with periodate oxidation and photometry. This should be much faster than the tedious acid dissolution with added fusion step needed to recover the retained analyte in the insoluble residue.

17.2 Determination of Phosphorus by Phospho-molybdenum Blue
The molybdate/magnesia method of Lundell, Hoffman and Bright has been the traditional method for reference analysis for determining phosphorus gravimetrically as magnesium pyrophosphate in minerals and iron ores. The method is quite tedious and cumbersome and suffers from titanium interference. The phosphovanadomolybdate photometric method also involves further extraction with methyl isobutyl ketone (MIBK) making it quite tedious and lengthy. Earlier the author developed a scheme for universal dissolution of materials encountered in the steel industry and its application for the photometric determination of arsenic, phosphorus, titanium and vanadium. This will be described in section 17.1. The scheme uses fusion with sodium peroxide in a zirconium crucible for the above mentioned elements except for phosphorus. It was thought that zirconium may bind phosphorus as insoluble zirconium phosphate. Hence to avoid zirconium interference, a separate fusion of the sample in a vitreous carbon crucible with sodium peroxide and sodium carbonate was made. The melt was dissolved in perchloric acid, the medium used for developing the final molybdenum blue color for the photometric determination of phosphorus. In our investigations perchloric acid concentration was found to be critical and the usual practice of adding bismuth was found unsuccessful. Further, the use of perchloric acid is becoming rarer, particularly in North America, owing to its hazardous nature and strict safety control required. In a later study it was established that fusion with sodium peroxide in a zirconium crucible and dissolution of the melt in hydrochloric acid is amenable to the development of phosphomolybdenum blue color by addition of molybdate and hydrazine. However the concentration of hydrochloric acid was found important and needed investigation. The following developed method was established and has been adapted as standard methods: (ISO 4687) and (ASTM E 1070).

17.2.1 Procedure
Accurately weigh sample (Table 2) following the test sample weighing procedure in section 8, into a dry 50-mL zirconium crucible, mix with 2 g of powdered sodium peroxide and fuse over a M’eker burner following the fusion dissolution procedure (section 13.1). Cool the crucible somewhat in air and place in a dry 250-mL beaker. Add 10 mL of water to the crucible and cover the beaker with a watch glass. After effervescence ceases, pour the contents of the crucible into the beaker and wash with 15–20 mL of water. Add 15 mL 12N HCl via the crucible as well as water rinsings into the beaker. Boil the solution for 2 min. Wash the watch glass and the walls of the beaker with water and continue boiling for about 30 s. Cool and transfer into a 50-mL volumetric flask, dilute the contents with water and mix.

17.2.1.1 Photometry
Transfer (Table 2) an appropriate aliquot and the fusion blank (prepared by dissolving 4 g sodium peroxide in 40 mL of water, adding 30 mL 12N HCl, boiling for 2 min, cooling and diluting to 100 mL in a volumetric flask) to a 150-mL beaker. Add 15 mL of sodium sulfite (100 g L\(^{-1}\)) solution, mix and bring to the boil. Add 20 mL of molybdate–hydrazine sulfite (section 17.2.1.2) solution, mix and bring to the boil then heat for 10 min in a boiling water-bath. Cool. Transfer to a 50-mL volumetric flask, dilute the mark with water and mix. Within the next 2 h measure the absorbance of the solution and the calibration standards (section 17.2.1.4) at 725 nm with water as reference. Subtract the blank to obtain the net absorbance.

Table 2 Phosphorus photometric: sample weight, aliquot and fusion blank additions to aliquot

and read off µg of phosphorus from the calibration graph. Calculation: \( \text{percent P} = \frac{\text{µg of phosphorus}}{0.005/\text{[sample aliquot (mL)]} \times \text{sample weight (g)}} \) [\( g \)].

### 17.2.1.2 Ammonium Molybdate–Hydrazine Solution

To prepare 500 mL of water, add cautiously and slowly 300 mL sulfuric acid and cool. Add 20 g of ammonium heptamolybdate tetrahydrate \([\text{(NH}_4\text{)}_6\text{Mo}_7\text{O}_{24} \cdot 4\text{H}_2\text{O}]\). Stir to dissolve and dilute to one litre with water. Add 50 mL of this solution to 100 mL of water, followed by 20 mL of hydrazine sulfate (1.5 g L\(^{-1}\)) solution, and dilute to 200 mL.

### 17.2.1.3 Standard Phosphorus Solution

Dry anhydrous disodium phosphate \((\text{Na}_2\text{HPO}_4)\) at 105 °C, cool in a desiccator, then dissolve 0.2292 g in 200 mL of water. Transfer and dilute to volume in a 1-L volumetric flask with water and mix. This is the standard “A” 50 µg mL\(^{-1}\) phosphorus solution. Transfer 10.00 mL of this solution into a 50-mL volumetric flask, dilute to mark with water and mix. This solution “B” is the 10 µg mL\(^{-1}\) phosphorus solution for calibration.

### 17.2.1.4 Preparation of Calibration Curve

Into a series of five 150-mL beakers transfer 10.00 mL portions of fusion blank solution and then 0.50 and 2.50 mL of “B” and 1.00 and 2.00 of standard “A” 50 µg mL\(^{-1}\) phosphorus solution, corresponding to 0, 5, 25, 50 and 100 µg of phosphorus respectively. To each beaker add 15 mL of sodium sulfite solution, and continue from this point as described in photometry (section 17.2.1.1), for the test solution. Plot the net absorbance [obtained by subtracting the blank (0 µg P) absorbance] against µg of phosphorus in the colored solution.

### 17.3 Determination of Silicon by Silico-molybdenum Blue

Silicon may be determined by measuring the absorbance of the yellow or blue color formed by silicon with molybdate ions, the sensitivity being higher for the reduced molybdenum blue complex. Sanders and Cramer\(^{(20)}\) studied various reducing agents such as tin(II) chloride, oxalic acid, iron(II) sulfate, sodium sulfite and 1-amino-2-naphthol-4-sulfonic acid. With iron(II), there is neither reduction of free molybdate nor interference from phosphorus or arsenic as there is with tin(II) chloride and it is not temperature-sensitive as is the case with sulfite. Finally, since iron is present in the iron samples anyway, it may as well be used as the reducing agent. In the method\(^{(21)}\) described, the sample is fused with sodium peroxide in a zirconium crucible and the melt is dissolved in HCl. An aliquot of the solution is treated with molybdate and the silicomolybdate complex formed, is reduced to molybdenum with iron(II). Fluoride is added to provide a redox buffering system. The method is eminently useful for automation and applied to autoanalyzers\(^{(21)}\) for universal photometric determination of silicon in multi-matrix such as iron ores, sinters, slags, iron and steel. Results are comparable to those obtained by reference methods as illustrated for various SRMs of iron ores and others of diverse composition. Only the manual photometric method is described in the following procedure.

### 17.3.1 Procedure

Accurately weigh a 0.2000 g sample, following the test sample weighing procedure in section 8, into a dry 50-mL zirconium crucible, mix with 2 g of powdered sodium peroxide and fuse over a M'eker burner following the fusion dissolution procedure (section 13.1). Add 10 mL of water to the crucible and cover the beaker with a watch glass. After effervescence ceases, pour the contents of the crucible into the beaker and wash with 15–20 mL of water. Add 30 mL of diluted (1 + 1) HCl via the crucible as well as water rinsings into the beaker. Boil the solution for 2 min. Wash the watch glass and the walls of the beaker with water and continue boiling for about 30 s and cool. Immediately transfer the solution to a 1-L volumetric flask and add about 500 mL of water and 40 mL of 8% v/v sulfuric acid with swirling and then dilute the contents with water and mix. Carry out a procedure blank exactly as described but omitting the sample.

#### 17.3.1.1 Photometry

Transfer 10.00 mL aliquot into a 50-mL volumetric flask containing 5 mL of 0.2% iron solution (prepared by dissolving 1.00 g of pure iron in 80 mL of 8% v/v sulfuric acid, adding 10 mL of 3% freshly prepared ammonium persulfate and boiling for 2 min, cooling and diluting to volume with water in a 500-mL volumetric flask). Add 10 mL of freshly prepared ammonium molybdate (1.6% w/v stored in a polyethylene bottle) solution and mix. After 3 min add 10 mL of sodium fluoride (2.4% w/v aqueous solution, stored in a polyethylene bottle). Mix well. Measure absorbance in a 10-mm cuvette with water as reference, at 665 nm. Subtract the procedure blank absorbance to obtain net absorbance to read off the percent Si in the sample.

#### 17.3.1.2 Calibration

Prepare calibration solutions using appropriate National Bureau of Standards (NBS), National Institute of Standards and Technology (NIST), British Chemical Standards (BCS) or local standard reference iron ore samples, and treat exactly as described under the procedure and photometry. Plot net absorbance against percent Si to obtain the calibration graph.
17.4 Determination of Titanium by Chromotropic Acid

Both the ISO method (ISO 4691) and ASTM (E 878) for determining titanium photometrically with diantipyrilmethane, use an acid dissolution followed by treatment and fusion of the insoluble residue. This makes the method unnecessarily time-consuming. The titanium treatment and fusion of the insoluble residue. This makes diantipyrilmethane, use an acid dissolution followed by Ti at the 0.5% level in the following procedure:

was found to be 0.001% Ti at the 0.03% level and 0.008% is stable for 16 h under the conditions of the procedure. Crucibles. The titanium complex with chromotropic acid results were obtained with zirconium or alternative nickel ing the fusion of the sample will not interfere. Identical V), do not interfere. Zirconium or nickel leached dur-

In some iron ore, including phosphorus (e.g. BCS 303: 0.5% P) and vanadium (e.g. Philippine iron sand: 0.3% V), do not interfere. Zirconium or nickel leached during the fusion of the sample will not interfere. Identical results were obtained with zirconium or alternative nickel crucibles. The titanium complex with chromotropic acid is stable for 16 h under the conditions of the procedure. For standard reference samples the standard deviation was found to be 0.001% Ti at the 0.03% level and 0.008% Ti at the 0.5% level in the following procedure.\(^{(15)}\)

17.4.1 Procedure

Accurately weigh 0.5000 g sample, following the test sample weighing procedure (section 8), into a dry 50-mL zirconium crucible, mix with 4 g of powdered sodium peroxide and fuse over a M’eker burner following the fusion dissolution procedure (section 13.1). Add 10 mL of water to the crucible and cover the beaker with a watch glass. After effervescence ceases, pour the contents of the crucible into the beaker and wash with 15–20 mL of water. Add 10 mL of concentrated HCl via the crucible as well as water rinsings into the beaker. Boil the solution for 2 min. Wash the watch glass and the walls of the beaker with water and continue boiling for about 30 s and cool. Transfer the solution to a 100-mL volumetric flask and dilute the contents with water to the mark and mix.

17.4.1.1 Photometry Transfer 10.00 mL aliquot into a 150-mL beaker. Add 10 mL of freshly prepared 5% ascorbic acid solution, mix, wait for 5 min, add 15 mL of freshly prepared 1% chromotropic acid solution and mix. Adjust (using a narrow-range pH paper) to pH 3.5–4.0 with acetate buffer (prepared by dissolving 220 g of sodium acetate trihydrate in water, adding 220 mL of glacial acetic acid and diluting the mixture to 1 L). Transfer to a 100-mL volumetric flask. Dilute to the mark with water. After 15 min measure absorbance at 470 nm in a 2-cm cuvette against water as reference. The color is stable for at least 2 h. Subtract the blank (0 calibration standard) to obtain net absorbance. Read off µg of titanium from the calibration graph. Calculate percent Ti by multiplying by 0.001 and dividing by sample weight in g.

17.4.1.2 Calibration Prepare fusion blank solution by weighing 0.300 g of pure iron powder into a zirconium crucible and carry out the procedure exactly. For the calibration, transfer 10.00 mL aliquot of fusion blank solution, into a series of 150-mL beakers. Add 0, 0.50, 1.0, 2.5, 5.0, 10.0 and 15.0 mL of 20 µg mL\(^{-1}\) titanium working solution (section 17.4.1.3). Carry out exactly as described in photometry (section 17.4.1.1). Plot net absorbance vs µg of titanium.

17.4.1.3 Standard Titanium Solution Fuse 0.1000 g of pure titanium (fine powder) with 2 g of potassium bisulfate in a platinum crucible at low heat. When clear melt is obtained, cool somewhat and dissolve the contents in 10 mL of diluted (1 + 1) H\(_2\)SO\(_4\). Dilute to 1 L in a volumetric flask and mix. Dilute 20.00 mL of this solution to volume with water in a 100-mL volumetric flask to obtain the 20 µg mL\(^{-1}\) titanium working solution.

17.5 Determination of Vanadium by N-benzoyl-phenylhydroxylamine

Photometric determination of vanadium by BPHA, in steel including highly alloyed steel and high-temperature alloys, has been in use for a long time. It was thought desirable to investigate the application of BPHA for determining vanadium in iron ores using the rapid fusion/dissolution technique. After fusion of the sample and dissolution of the cooled melt in dilute sulfuric acid, vanadium was oxidized with permanganate and determined photometrically with BPHA. The critical point is ensuring oxidation of vanadium to the quinquevalent state before addition of HCl and subsequent extraction and color formation with BPHA. This is achieved in the described method.\(^{(15)}\) Precision tests on two South African reference standard iron ores (10 replicates each) gave a standard deviation of 0.001% V at the 0.005% level and 0.002% V at the 0.05% level. Excellent agreement was found between the certified values Japan SRM 830-1: 0.31% V; 850-1: 0.05% V and South African SRM 11: 0.004% V; and SRM 12: 0.052% V; and those found with the procedure described as follows.

17.5.1 Procedure Accurately weigh a 0.5000 g sample, following the test sample weighing procedure (section 8), into a dry 50-mL zirconium crucible, mix with 4 g of powdered sodium peroxide and fuse over a M’eker burner following the
fusion/dissolution procedure (section 13.1). Add 20 mL of water to the crucible and cover the beaker with a watch glass. After effervescence ceases, pour the contents of the crucible into the beaker and wash with 10 mL of water. Add 30 mL of diluted (1 + 4) sulfuric acid via the crucible as well as water rinsing into the beaker. Add 100 mL of diluted (1 + 4) sulfuric acid, then 1 or 2 drops of hydrogen peroxide until the color is clear yellow. Boil the solution for 2 min. Wash the watch glass and the walls of the beaker with water and continue boiling for about 30 s and cool. Transfer the solution to a 200-mL volumetric flask. Dilute the contents with water to the mark and mix.

17.5.1.1 Photometry Transfer an appropriate aliquot into a 125-mL separating funnel (25 mL for 0.001–0.1% V, 10 mL for 0.1–0.2%, 5 mL for 0.2–0.5%, plus enough fusion blank solution (section 17.5.1.2) to give a total volume of 25 mL). Add 0.3% potassium permanganate (about 0.1 N) solution dropwise until a faint pink persists for 2 min, and then three drops more. Wait for 2 min. Add 20 mL of concentrated HCl and mix. Add 10 mL of freshly prepared BPHA (0.25% solution) in chloroform, and shake the funnel for 45 s. Let the layers separate; draw off the organic phase into a dry 50-mL beaker. Shake the aqueous phase in the funnel with 10 mL of chloroform for 30 s and draw off the organic layer in the beaker. Transfer the combined organic extracts into a dry 50-mL volumetric flask and make up the volume with chloroform. Measure the absorbance (within the next 2 h) in 1-cm cuvette at 530 nm against chloroform as reference. Subtract the blank (0-calibration) to obtain the net absorbance. Read off µg of vanadium from the calibration graph. Calculate percent V by multiplying µg of vanadium by 0.005 and dividing by sample weight (g) multiplied by sample aliquot (mL).

17.5.1.2 Calibration Prepare fusion blank solution by weighing 1,300 g of pure iron powder into a zirconium crucible, add 8 g of sodium peroxide and continue exactly as in the procedure. For the calibration curve, pipette 25 mL fusion blank solution into a series of 125-mL separating funnels. Add 0 (0 blank), 0.25, 0.5, 1.0, 2.0, 4.0, and 5.0 mL of 50 µg mL⁻¹ vanadium working solution (section 17.5.1.3) and enough water to make up the volume to 30 mL. Beginning from oxidation with potassium permanganate, continue exactly as described in photometry. Plot net absorbance against µg of vanadium.

17.5.1.3 Standard Vanadium Solution Weigh 0.230 g of ammonium metavanadate (NH₄VO₃) into a 150-mL beaker. Add 60 mL of water and gently simmer to dissolve. Cool, add 1 mL of concentrated sulfuric acid and dilute with water to the mark in a 100-mL volumetric flask. Pipette 5 mL of this solution into a 100-mL volumetric flask containing 50 mL of water and 1 mL of concentrated sulfuric acid and dilute with water to the mark in a 100-mL volumetric flask to obtain the working solution (V, 50 µg L⁻¹).

17.6 Determination of Arsenic by Silver Diethylthiocarbamate–Ephedrine

In the past, reagents such as quercetin, morin and rutin have been employed for the photometric determination of arsenic as well as distillation separation as arsenic trichloride(24,25) and the subsequent formation of the arsenomolybdenum color complex. The present development is essentially based on the rapid photometric method(26) for the determination of arsenic in steel by absorbing the evolved arsine in silver diethylthiocarbamate. It was established that the concentration of sulfuric acid and other parameters must be kept constant to avoid an erratic yield of arsenic and subsequent erratic results. In the universal fusion dissolution technique for iron ores, treating the fused melt with HCl and fuming with sulfuric acid leaves inconsistent amounts of the latter. It is more reliable to avoid fuming by dissolving the melt directly in dilute sulfuric acid for subsequent reduction with potassium iodide and stannous chloride in the photometry of the evolved arsine with silver diethylthiocarbamate to obtain precise and accurate results. The procedure described(5) also replaces the obnoxious smelling pyridine by substituting ephedrine in chloroform as solvent for silver diethylthiocarbamate. The procedure is as follows.

17.6.1 Procedure

Run the test sample(s) and calibration standards simultaneously (taking identical sample weight and fusion in a zirconium crucible similar to calibration standards). Prepare calibration standards as follows: into each of six zirconium crucibles weigh 0.500 g of pure ferric oxide and 3 g of sodium peroxide for the range 0.0002–0.01% As or 0.05 g of ferric oxide and 1 g of sodium peroxide for the range 0.01–0.10% As. Mix thoroughly and carry out fusion for each crucible over a M’eker burner following the fusion/dissolution procedure (section 13.1). Cool the crucibles somewhat in air and place each in a separate dry 250-mL beaker. Add 10 mL of water into the crucible and cover the beaker with a watch glass. After effervescence ceases, pour the contents of the crucible into the beaker and rinse with 10 mL of water. Add 20 mL of diluted (1 + 1) sulfuric acid via the crucible as well as 10 mL of water. Transfer 0.30, 0.50, 1.00, 2.00 and 5.00 of the 10 µg mL⁻¹ of arsenic working solution (section 17.6.1.1) into the beakers, avoiding any contamination with the simultaneously treated test sample(s). Gently boil the solutions for about 2 min. Cool. At this point the series of arsenic generation
and absorption apparatus described, should be made ready by placing a small plug of lead acetate cotton (section 17.6.1.2) in position, connecting the capillary delivery tube removing the “inner joints” with the capillary tubes attached.

17.6.1.1 Arsenic Standard and Working Solution Dissolve 0.6601 g of arsenic trioxide (As$_2$O$_3$) in 20 mL of 20% w/v sodium hydroxide solution and dilute to 1 L with water in a volumetric flask. Dilute 10.00 mL of this solution (As = 500 $\mu$g mL$^{-1}$) to the mark with water in a 500-mL volumetric flask. This working solution (As = 10 $\mu$g mL$^{-1}$) is stable for at least a month.

17.6.1.2 Lead Acetate Cotton Dissolve 30 g of lead acetate trihydrate in 300 mL of water and make just acid with acetic acid. Soak absorbent cotton in this solution. Allow excess to drain out, then dry at 110°C.

17.6.2 Photometry

Transfer the solutions to the respective generation flasks (test sample(s) and calibrations standards) with a minimum of water. To each flask add freshly prepared 15% potassium iodide solution, mix and let stand for 5 min. Add 40% stannous chloride (40 g SnCl$_2$ · 2H$_2$O in concentrated HCl and diluted to 100 mL with concentrated HCl) solution dropwise with swirling until the iron and the liberated iodine have been reduced (solution becomes colorless), then add five drops in excess. Let stand for 15 min. Meanwhile pipette 5 mL of arsenic-absorption solution (section 17.6.2.1) into the absorption test-tubes. Quickly introduce 3.0 g of arsenic-free 20-mesh granulated zinc into the flask through a short-necked funnel and immediately fit the delivery and absorption system. Periodically swirl the flask. Let stand until no further gases are evolved (about 15–20 min). The funnel prevents any zinc from adhering to the ground glass joint (which would prevent a gas-tight seal). Immediately measure the absorbance in 1-cm cuvette at 540 nm against the arsenic-absorption solution as reference. Subtract the blank (0-calibration) to obtain the net absorbance. Read off $\mu$g of arsenic by multiplying $\mu$g of arsenic by 10$^{-4}$ and dividing by sample weight (g).

17.6.2.1 Arsine Absorption Solution Dissolve 0.41 g of ephedrine in 250 mL chloroform. Weigh 0.20 g of silver diethylidithiocarbamate into a 400-mL beaker, add a few milliliters of the ephedrine solution to make a paste, then add the remainder and stir to dissolve. Store in a glass-stopped amber-colored bottle, away from light. Filter, if necessary, before use.

18 FLAME ATOMIC ABSORPTION SPECTROMETRIC METHODS

As indicated earlier, FAAS methods are used for elements such as Ca, Mg, Cu, Zn, Pb, Na, K, Ni and Cr. Prior to the advent of FAAS the wet chemical methods for determination of Na and K, particularly the Lawrence Smith method, were very tedious and of questionable accuracy. Basically, in FAAS technique, a solution containing a metal species is aspirated into a flame such as air/acetylene or nitrous oxide/acetylene. Some of the atoms may be thermally excited from the ground state for emission of characteristic radiation; however, most of the atomic population remains in the ground state capable of absorbing light energy of specific wavelengths corresponding to excitation to higher atomic energy levels. Hence if light from these wavelengths is passed through a flame containing atoms of the element (e.g. hollow cathode lamp), part of the energy will be absorbed and the absorption will be proportional to the concentration of these atoms in the flame. The instrument must meet the criteria for minimum sensitivity, curve linearity and minimum stability. Instrument manufacturer’s safety instructions including igniting and extinguishing the nitrous oxide burner and recommended parameters for optimization etc. should be strictly followed. Acid dissolution sometimes leaves some analyte trapped in the insoluble residue and needing to be recovered by fusion dissolution. Examples of these procedures for Ca, Mg, will be described (section 18.1.1). Interference from some elements particularly the major element iron, is not uncommon; the latter needs to be separated by methods such as solvent extraction. Examples of two such methods, involving solvent extraction separation of iron, i.e. combined procedures for Pb/Zn (section 18.3.1) and Cr/Ni (section 18.4.1), will be described.

18.1 Determination of Calcium and Magnesium

The old tedious gravimetric methods for the determination of calcium (precipitation as calcium oxalate, ignited to CaO) and magnesium (precipitated as magnesium ammonium phosphate, ignited as magnesium pyrophosphate)$^{(2)}$ are hardly in use. A rapid scheme (unpublished) was devised for the anion exchange separation of iron and then determination of calcium and magnesium complexometrically. However these methods have now been superseded by FAAS, for both routine and reference analysis. The sample is dissolved in HCl and a small amount of HNO$_3$. After evaporation and dehydration, any insoluble matter is filtered, treated for the recovery of calcium and magnesium and added to the main solution. The solution is aspirated into the flame of the atomic absorption spectrometer.
A nitrous oxide/acetylene burner is used for calcium and an air/acetylene burner for magnesium. For calcium, a calcium-hollow cathode lamp and 422.7 nm (wavelength) are chosen. For magnesium, a magnesium-hollow cathode lamp and 285.2 nm (wavelength) are used. The following procedure details an example of acid dissolution in a FAAS method where the trapped insoluble analyte is recovered, but removal of iron is unnecessary.

### 18.1.1 Procedure

Weigh 1.000 g, sample as described in section 8 (test sample weighing procedure), and transfer to a 250-mL beaker. Carry a reagent blank through all steps of the procedure. Moisten the sample with a little water. Add 25 mL of HCl. Cover with a watch glass and then gently increase the heat to just below boiling until reaction ceases. Add 2 mL of HNO₃, digest for several minutes, evaporate to dryness and heat the salts for a few minutes. Add 5 mL of HCl, cover the beaker and warm for a few minutes. Add 50 mL of water and heat to dissolve the salts. Filter through a fine-texture filter paper collecting the filtrate in a 250-mL beaker. Wash the filter and residue alternately three times with hot diluted (1 C 9) HCl and hot water until the yellow color of ferric chloride is no longer apparent. Reserve the filtrate. Place the paper and residue in a platinum crucible and char it at 500 °C in a muffle furnace and then ignite at 700 °C for a few minutes. Cool the crucible. Add four drops of diluted (1 C 1) H₂SO₄ to moisten the residue in the crucible. Add 5 mL of HF. Cautiously and slowly heat to the absence of white SO₃ fumes. Cool, add 1 g of sodium carbonate and fuse over a M'eker burner until a clear melt is obtained. Cool the melt and dissolve it in the reserved filtrate. Remove and wash the crucible and cover. Cool. Transfer to a 200-mL volumetric flask, dilute with water to the mark and mix. Proceed with the measurements described in section 18.1.2.

### 18.1.2 Calibrations, Reagents and Measurements for Flame Atomic Absorption Spectrometry

**Calcium standard solution (1 mL = 25 µg Ca):** dissolve 1.2487 g anhydrous calcium carbonate in 100 mL of diluted (1 + 3) HCl. When solution is complete, cool and dilute to volume with water in a 1-L volumetric flask. Transfer 10.00 mL of this solution to a 200-mL volumetric flask, dilute to the mark with water and mix.

**Magnesium standard solution: (1 mL = 17.5 µg Mg):** dissolve 0.3500 g of high-purity magnesium metal by slowly adding 75 mL of diluted (1 + 3) HCl. When solution is complete, cool and dilute to volume with water in a 1-L volumetric flask. Transfer 10.00 mL of this solution to a 200-mL volumetric flask, dilute with water to the mark and mix.

**Background solution:** dissolve 10.00 g of high-purity iron powder in concentrated HCl and oxidise with dropwise addition of HNO₃. Evaporate to a syrupy consistency, add 20 mL of HCl and dilute to 200 mL with water. Add 20 g of sodium chloride dissolved in 200 mL of water and dilute to volume with water in a 1-L volumetric flask.

**Lanthanum chloride solution (50 g L⁻¹):** dissolve 50 g of lanthanum chloride in 50 mL of HCl and 300 mL of hot water. Cool and dilute to volume with water in a 1-L volumetric flask.

**Calcium and magnesium calibration standard solutions:** transfer 5.00, 10.00, 20.00, 40.00, and 50.00 mL each of calcium and magnesium standard solutions to a series of 200-mL volumetric flasks. Dilute to 100 mL with water. Add 6 mL of HCl, 60 mL of background solution, 40 mL of lanthanum chloride solution, dilute to the mark with water and mix.

**Zero calibration solution:** transfer to a 200-mL volumetric flask 60 mL of background solution. Add 6 mL of HCl, 40 mL of lanthanum chloride solution, dilute to mark with water and mix.

Measurements: light the burner and aspirate water until the instrument comes under thermal equilibrium. Optimize the instrument response by adjusting the wavelength, fuel, (nitrous oxide/acetylene for Ca or air/acetylene for Mg) burner and nebulizer while...

aspirating the highest calcium or magnesium calibration solution to obtain the maximum absorbance. Aspirate water until a steady signal is obtained and adjust the instrument readout system to obtain zero absorbance. Aspirate the calcium or magnesium calibration standard solutions in the order of increasing absorbance starting with the zero calibration solution. Record the readings. Aspirate the test solutions at the proper points in the calibration series. Aspirate water between each calibration and test solution. Repeat all absorbance measurements at least two or more times. Obtain the net absorbance of each calibration solution by subtracting the average absorbance of the zero calibration solution. Similarly obtain the net absorbance of test solutions by subtracting the average absorbance of the reagent blank solution. Prepare a calibration curve for calcium and magnesium by plotting the net absorbance of the calibration solutions against micrograms of calcium or magnesium per mL. Convert the net absorbance values of the sample solutions to micrograms of calcium or magnesium per mL.

Calculation: calcium or magnesium percent = \( \frac{A}{B} \) where \( A \) = micrograms of calcium or magnesium per mL and \( B \) = sample represented in the 200-mL volume of the final test solution.

18.2 Determination of Copper

Range 0.003 to 1.0%: prior to the advent of FAAS, copper had been determined photometrically with reagents such as diethylthithiocarbamate and also by a specific reagent dithizone methods for lead and zinc have questionable accuracy. In order to carry out the dithizone method, the sample is decomposed by HCl, HNO₃, HF and fumed after the addition of HClO₄. After dissolving the salts, filtration and dilution with water, copper is determined by FAAS using an air/acetylene flame technique using a copper-hollow cathode lamp at the resonance wavelength Cu 324.7 nm and steps similar to the calcium/magnesium procedure (section 18.1.1).

18.3 Determination of Lead and/or Zinc

Range 0.001 to 0.5% Pb and Zn. The lead molybdate gravimetric method for lead and the photometric dithizone methods for lead and zinc have questionable accuracy. In order to carry out the dithizone method, extensive separation of lead and zinc and other dithizone-complex forming elements need to be carried out. An anodic stripping voltammetric method for the simultaneous determination of cadmium, copper, lead and zinc in iron ore, sinter etc. was devised for monitoring, for a research project. The FAAS method for lead and/or zinc by FAAS, though tedious, is preferable in terms of accuracy and precision. The sample is dissolved in HCl and HF, oxidized with HNO₃, filtered and the residue reserved. After evaporation the salts are dissolved in HCl, filtered and the filtrate evaporated to dryness and salts redissolved in HCl. Iron is then removed by MIBK solvent extraction. Lead and zinc are extracted into the aqueous phase which is treated with HNO₃ to destroy any organic matter and then evaporated to dryness. The reserved residue is ignited, fused with sodium carbonate, the melt dissolved in dilute HCl and then this solution is finally added to the evaporated and dried extracted lead and/or zinc. This solution is ready for aspiration into the flame of FAAS, using an air/acetylene burner, lead- and zinc-hollow cathode lamps and absorbance measurement at the respective resonance wavelength (Pb 283.3 nm) and (Zn 213.9 nm).

18.3.1 Procedure

Weigh 2000 g as described in section 8 (test sample weighing procedure) and transfer to a 250-mL polytetrafluoroethylene (PTFE) beaker. Carry a reagent blank through all steps of the procedure. Moisten the sample with a little water. Add 40 mL of HCl and 10 mL of HF. Cover with a PTFE cover, heat gently and then increase the heat to 200°C. Evaporate to dryness. Add 5 mL of HNO₃ and evaporate to dryness again. Dissolve the salts with 5 mL of HCl. Add 10 mL of water and filter through a fine-texture filter paper collecting the filtrate and washings into a 250-mL beaker. Wash the filter and residue with diluted (2+98) HCl until free from the yellow iron stain and then three times with hot water. Reserve the residue and combined filtrate and washings.

18.3.1.1 Treatment of Residue

Place the paper and residue in a platinum crucible and char at 500°C in a muffle furnace. Add 0.5 g of sodium carbonate and fuse over a Meker burner until a clear melt is obtained. Cool the melt, add 5 mL of HCl, heat to dissolve and reserve the solution.

18.3.1.2 Treatment of Combined Filtrate and Washings and Removal of Iron

Evaporate the filtrate and washings (section 18.3.1) just to dryness and add 20 mL of diluted (10+6) HCl and transfer to a 200-mL separating funnel. Rinse the beaker with 20 mL of diluted (10+6) HCl and combine with the solution in the separating funnel. Add 50 mL of MIBK and shake thoroughly for 1 min. Allow the layers to separate, then run the lower aqueous phase into a 250-mL beaker. Wash the organic phase by extracting with 10 mL of diluted (10+6) HCl and transfer the washings to the beaker. Heat the solution gently to expel almost all of the MIBK in the solution. Then add 5 mL of HNO₃ and evaporate to dryness. Dissolve the salts in 15 mL of diluted HCl (1+1). Combine this solution with the reserved solution from section 18.3.1.1. Transfer this solution to a 50-mL volumetric flask, dilute to the mark with water.

and mix. Depending on the concentration of lead and zinc (dilution and reagent guide Tables 4 and 5), use this solution for FAAS measurements either without dilution, or as specified. If dilution is required, transfer the appropriate aliquot to a 250-mL beaker. Add the amount of sodium carbonate and diluted HCl (1 + 1) as indicated for lead (Table 4) and for zinc (Table 5). Heat the solution to expel carbon dioxide. Cool and transfer the solution to a 100-mL volumetric flask, dilute to the mark with water and mix. Dilutions shown in Tables 4 and 5 will provide percent lead/zinc falling within the range of the calibration solutions in section 18.3.1.3. Transfer corresponding amounts of blank test solution to 250-mL beaker and add the same amount of sodium carbonate and diluted HCl (1 + 1) as used for the test solution. Heat the solution to expel carbon dioxide. Cool and transfer the solution to a 100-mL volumetric flask and dilute to the mark with water and mix. This solution is the diluted blank test solution.

18.3.1.3 Calibration Solutions, Reagents, and Measurements for Flame Atomic Absorption Spectrometry

Lead standard solutions: dissolve 0.5000 g of high-purity lead metal in 40 mL of diluted (1 + 1) HNO₃. Cool. Transfer to a 500-mL volumetric flask, dilute with water to volume and mix. This stock solution contains 1 mg of Pb per mL. Prepare standard solution “A” by transferring 10.00 mL of stock solution to a 100-mL volumetric flask, dilute to the mark with water and mix. Standard solution “A” contains 0.10 mg of Pb per mL. Prepare standard solution “B” by transferring 10.00 mL of standard solution “A” to a 100-mL volumetric flask, dilute to the mark with water and mix. Standard solution “B” contains 0.010 mg of Pb per mL.

Zinc standard solution: dissolve 0.5000 g of high-purity zinc metal in 40 mL of diluted (1 + 1) HCl. Cool. Transfer to a 500-mL volumetric flask, dilute with water to volume and mix. This stock solution contains 1 mg of Zn per mL. Prepare standard zinc solution by transferring 10.00 mL of stock solution to a 1000-mL volumetric flask, dilute to the mark with water and mix. This standard zinc solution contains 0.010 mg of Zn per mL.

Preparation of calibration solutions for lead: to a series of six 250-mL beakers transfer 1.0 g of sodium carbonate. Add 20 mL of HCl and transfer 0.0 (zero solution); 20.00 mL of standard solution “B”; and 5.00, 10.00, 15.00 and 20.00 mL of standard solution “A” respectively. Heat the solution to expel carbon dioxide. Cool and transfer the respective solutions to a series of six 100-mL volumetric flasks, dilute to the mark with water and mix. Preparation of calibration solutions for zinc: to a series of six 250-mL beakers transfer 1.0 g of sodium carbonate. Add 20 mL of HCl and transfer 0.0 (zero solution), 5.00, 10.00, 15.00, 20.00 and 25.00 mL of zinc standard solution respectively. Heat the solution to expel carbon dioxide. Cool and transfer the respective solutions to a series of six 100-mL volumetric flasks, dilute to the mark with water and mix.

Measurements: follow instrument set up and absorbance measurement exactly as in section 18.1.2, using appropriate wavelengths (Pb 283.3 nm; Zn 213.9 nm) and air/acetylene burner. Prepare calibration curves for lead or zinc by plotting the net absorbance of the calibration solutions against mg mL⁻¹ of Pb or Zn. By referring to the calibration graph convert the net absorbance value of the test solution or diluted test solution to mg mL⁻¹ of Pb or Zn. Calculate percent lead or zinc in the sample, commensurate with sample dilution.
18.4 Determination of Nickel and/or Chromium

As indicated in section 18, the FAAS method for the determination of nickel and/or chromium also involves the prior separation of iron by solvent extraction as described in detail in the procedures in section 18.3.1. For brevity, only the outline is described. The sample is dissolved in HCl and oxidized with HNO₃, and the filtered residue is reserved. After evaporation the salts are dissolved in HCl, filtered, the filtrate evaporated to dryness and salts redissolved in HCl. Iron is then removed by MIBK solvent extraction. Nickel and/or chromium are extracted into the aqueous phase which is then treated with HNO₃ to destroy any organic matter and evaporated to dryness. The reserved residue is ignited, fused with sodium carbonate–sodium tetraborate, and the melt dissolved in dilute HCl. This solution is finally added to the evaporated and dried extracted metal/s. This solution is ready for aspiration into the flame of FAAS, using an air/acetylene burner for nickel and a nitrous oxide/acetylene burner for chromium along with Ni- and Cr-hollow cathode lamps with absorbance measurement at resonance wavelengths Ni 232.0 nm and Cr 357.9 nm, respectively.

18.5 Determination of Sodium and Potassium

As indicated earlier, prior to the advent of FAAS, methods for the determination of these elements were tedious and somewhat unreliable. The FAAS method is quite straightforward. It is important to avoid contamination of sodium by glass apparatus. In brief, the sample is decomposed by HCl and HF in a PTFE beaker and evaporated to dryness. The treatment with HCl is repeated. After dissolution with HCl followed by appropriate dilution (in plastic volumetric flasks etc.), sodium and potassium are determined by FAAS using an air/acetylene flame using sodium- and potassium-hollow cathode lamps at the resonance wavelengths Na 589.0 nm and K 766.5 nm, respectively.

19 INDUCTIVELY COUPLED PLASMA/ATOMIC EMISSION SPECTROMETRY FOR MULTI ELEMENTS

With the ever increasing demand for rapid analytical control simultaneous determination of several elements is preferred. The ICP/AES technique uses solution and is generally used for minor elements. The iron ore sample is decomposed by fusion in a mixed sodium carbonate/sodium tetraborate flux and the melt dissolved in HCl. After dilution to volume the measurements are made on an ICP spectrometer for elements in iron ore, such as Al, Ca, Mg, Mn, P, Si, and T, and referred to calibration graphs using standard solutions. A procedure blank is carried out side by side for blank correction.

19.1 Procedure

Add 0.80 g of sodium carbonate to a 40-mL capacity platinum crucible or a suitable platinum-alloy crucible. Weigh 0.5000 g sample, as described in section 8 (test sample weighing procedure), transfer to the crucible and mix well with a platinum or stainless steel rod. Add 0.40 g of sodium tetraborate and repeat the mixing with the metal rod. Prefuse over a low dull red heat on a Bunsen burner with manual agitation. The mixture melts within 2–3 min. After this prefusion, place the crucible in a muffle furnace at 1020°C for 15 min. Remove the crucible and gently swirl the melt as it solidifies. Allow to cool and the place a PTFE-coated stirring bar in the crucible and place the crucible in a 250-mL low-form beaker. Add 40 mL of diluted (1 + 1) HCl directly into the crucible, and 30 mL of water into the beaker. Cover and heat with stirring on a magnetic stirring hot plate until dissolution of the melt is complete. Remove and rinse the crucible and stirrer. Cool the solution and immediately transfer (to prevent reprecipitation) to a 200-mL volumetric flask. Dilute to volume with water and mix. Carry out a procedure blank side by side.

19.1.1 Calibration Solutions, Reagents and Measurements

Aluminum standard solution (1 mL = 1 mg Al): dissolve 1.000 g of high-purity aluminum in 20 mL of diluted (1 + 1) HCl in a covered beaker. Add about 10 drops of HNO₃. When dissolution is complete, add 20 mL of water and boil to expel oxides of nitrogen. Cool and transfer to a 1000-mL volumetric flask, dilute to the mark with water and mix.

Calcium standard solution (1 mL = 1 mg Ca): dissolve 2.4972 g of anhydrous calcium carbonate in 20 mL of diluted (1 + 1) HCl. When solution is complete, add 20 mL of water and boil to expel oxides of nitrogen. Cool and transfer to a 1000-mL volumetric flask, dilute to the mark with water and mix.

Magnesium standard solution (1 mL = 1 mg Mg): dissolve 1.000 g of high-purity magnesium metal by slowly adding 20 mL of diluted (1 + 1) HCl. When solution is complete, cool, dilute to volume with water in a 1-L volumetric flask and mix.

Manganese standard solution (1 mL = 1 mg Mn): dissolve 1.000 g of high-purity manganese metal by slowly adding 20 mL of diluted (1 + 1) HCl. When solution is complete, cool, dilute to volume with water in a 1-L volumetric flask and mix.
Phosphorus standard solution (1 mL = 1 mg P): dry potassium dihydrogen orthophosphate (KH₂PO₄) at 110 °C, cool it in a desiccator. Dissolve 4.3936 g in 200 mL of water. Transfer and dilute to volume in a 1-L volumetric flask with water and mix.

Silicon standard solution (1 mL = 1 mg Si): weigh 2.1393 g of pure silicon dioxide (finely ground, previously heated at 1000 °C for 45 min) into a platinum crucible. Mix with 5 g of sodium carbonate and fuse in a muffle furnace for 15 min at 1000 °C. Cool somewhat and dissolve the melt in 100 mL of water. Transfer to a 1-L volumetric flask, add about 400 mL of water and mix. Add 20 mL of diluted (1 + 1) HCl, dilute to volume with water and mix.

Titanium standard solution (1 mL = 1 mg Ti): dissolve 1.000 g of high-purity titanium metal in 100 mL of water. Transfer and dilute to volume in a 1-L volumetric flask and mix.

Calibrations and reference solutions: for each of the elements Al, Ca, Mg, Mn, P, Si and Ti, prepare calibration solutions following the procedure in section 18.1, replacing the test sample with the equivalent amount of iron oxide (Fe₂O₃) of minimum purity 99.99%. Prior to dilution to 200 mL, the stock solution (element concerned) and diluted (1 + 1) HCl are added in sufficient amounts to retain the final acid concentration [40 mL of diluted (1 + 1) HCl]. In addition, to comply with the requirements of similarity, calibration solutions are prepared from reagents taken from the same containers, to minimize purity differences between batches.

Measurements: any conventional ICP spectrometer may be used. Set up according to manufacturer’s recommendation and ensure compliance with the performance parameters (Table 6) to be carried out prior to measurements. Suggested analytical lines performance parameters are shown in Table 6. The correction method for spectral interferences using synthetic standard solutions is recommended. Instrument manufacturers may provide software for various calculations (statistics) and algorithms for correction for inter-elemental spectral interferences etc. After instrument set up, aspirate water until a steady signal is obtained and adjust the instrument read out system to obtain zero absorbance. Aspirate the calibration standard solutions in the order of increasing absorbance, starting with the zero calibration solution. Record the readings. Aspirate the test solutions at the proper points in the calibration series. Aspirate water between each calibration and test solution. Repeat all measurements at least two or more times. Obtain the net intensity of each calibration solution by subtracting the average intensity of the zero calibration solution. Similarly obtain the net intensities of test solutions by subtracting the average intensity of the reagent blank solution. Prepare a calibration curve for the element(s) by plotting the net intensity of the calibration solutions against micrograms of element per mL. By referring to the calibration graph, convert the net intensity value of the test solution to micrograms of element per mL for calculating percent element(s) in the sample.

### 20 X-RAY EMISSION SPECTROMETRY

Single as well as several elements are determined by sequential and/or simultaneous modes by this technique, used primarily for routine control. In brief, the sample is irradiated by an intense beam of X-ray photons, which may impinge on atom/s in the sample resulting in the characteristic fluorescence wavelengths spectra. The beam of fluorescent radiation, characteristic of some or all of the elements in the sample, is then resolved into its constituents through an analyzing crystal, e.g. lithium fluoride. The X-ray quanta of this characteristic monochromatic wavelength are collimated on a radiation detector such as a scintillation or proportional counter, which translates them into voltage pulses integrated over a fixed period of time. This electrical output is proportional to concentration of the element in the sample. The pressed powder technique using a binder for iron ore sample preparation, is hardly used, owing to inherent matrix problems. For quantitative analysis, the finely ground iron ore sample is fused with borax. The fused melt is poured into a platinum dish to form a flat bead ready for XRF measurements. Calibrations are prepared using iron ore certified reference materials (CRMs). Inter-elemental corrections and correlation coefficients are calculated by making fused beads of binary mixture (element plus pure ferric oxide).

#### 20.1 Procedure

Add 8.00 g of borax (sodium tetraborate: prescreened stock) and 0.480 g sample into a glass vial. Cover the vial with a plastic snap and shake the vial to mix the borax

and sample. Transfer the contents quantitatively to a platinum : gold (95 : 5) alloy crucible. Using a micropipette add 0.100 mL of sodium iodide solution (0.25 g mL\(^{-1}\)) and fuse at 1200 °C for 15 min. (Automated fusion apparatus is preferable.) Pour the melt on a heated platinum dish to form a flat and uniform bead, then air cool. Carry out XRF measurements using an appropriate analyzing crystal and detector.

20.1.1 Measurements

Table 7 lists suggested parameters for XRF analysis in conjunction with a rhodium target in the X-ray tube. Fused beads of binary mixtures (element plus pure ferric oxide) are prepared for the sought element, identically to the procedure to compute inter-elemental correlation coefficients. Prepare standards for calibrations, using fused beads of iron ore SRMs/CRMs, exactly as in the procedure. Store the fused beads in a desiccator to avoid exposure to humidity. Plot percent element vs counts or intensity ratios and compute the concentration of element(s).

21 STANDARD/CERTIFIED REFERENCE MATERIALS, QUALITY CONTROL AND QUALITY ASSURANCE

It should be noted that SRMs and CRMs are used interchangeably in this article. Any use of a SRM depends on the ability to make valid inferences from the measurement results. This involves the tacit assumption or demonstrated evidence that the material is reliable and capable of challenging the measurement process. For quality assurance and quality control SRMs are used. Instrumental methods require SRMs for calibration. The latter are available from producers of SRMs such as NIST, British Standards, Euro Standards, Australian and Japanese Standards Institutions, etc. A useful resource is the NIST Special Publication 260-100\(^{(20)}\). It is important for the SRM users to be aware of the verification and accuracy of reference test methods used in the development of SRMs as well as the establishment of measurement traceability. Assurance of measurement compatibility is crucial for direct calibration of methods and instruments as well as internal and external quality assurance.

22 STATISTICS, ACCURACY AND PRECISION

These are an integral part of the establishment of analytical methods. Accuracy or trueness refers to the closeness of agreement between the arithmetic mean of large number of test results and the true or accepted reference value. Precision refers to the closeness of agreement between test results. Many factors, apart from variations between supposedly identical specimens, may contribute to the variability of results for an analytical method. These include, the operator; the equipment used; the calibration of the equipment; the environment (temperature, humidity, air pollution, etc.); the time elapsed between measurements. Statements for repeatability and reproducibility are essential indicators for the analysis as well as for quality control and quality assurance systems in the analytical laboratory. Standards on statistics, e.g. ISO 5725\(^{(30)}\) and ASTM E 173\(^{(31)}\) are useful for assessing these valuable statistics on analytical method performance, particularly the extensive round robin testing carried out for establishing standard methods.

Metal Analysis, Sampling and Sample Preparation in

Charles K. Deak
C.K. Deak Technical Services, Inc., Warren, USA

1 INTRODUCTION

When a metal is analyzed to establish its chemical composition, it is almost impossible and completely impractical to analyze the entire piece or lot of metal. Only a portion of the metal is analyzed, referred to as a sample. In fact, a distinction must be made between several forms of sample. According to the proper nomenclature there are several kinds of sample:

- A sample is a portion of the material intended to be representative of the whole.
- A gross sample is a single large sample obtained by placing in a single container two or more increments taken from a lot.
- A prepared sample is a sample on which comminution, division, blending, or other procedures have been performed to make the sample ready for analysis.
- A laboratory sample is a subsample selected from the properly prepared gross sample of the lot for submission to one or more laboratories for chemical analysis where select is understood to mean: to mix and divide a sample (with or without comminution) to ensure that the subsample equally represents the original lot.
- A test sample is a subsample selected from the properly prepared laboratory sample which has a suitable sample weight or volume for one or more determinations by chemical analysis.

The laboratory sample that it is going to be analyzed has two basic requirements. First, the sample, regardless of whether it is a gross sample, prepared sample, laboratory sample, or test sample, has to be representative of the entire piece or lot of metal. In other words, the chemical composition of the sample must be identical to the metal it represents. This is a simple matter if the metal that the sample is to represent is completely homogeneous and any portion of the metal to be analyzed has exactly the same composition as any other portion. Then, any single portion, wherever it is taken from, would be a good representative sample. In the practical world, such perfect homogeneity does not normally exist and even if it does exist its existence cannot be assured until extensive tests are done. As a result, it is the sampling procedures and equipment that have to provide for the fact that
the material is heterogeneous. Sampling procedures and equipment will be discussed in section 2.

The second requirement for a sample is that it should be suitable for analysis by the method chosen to perform the analysis or determination. For example, if the analysis of a metal is by atomic absorption spectroscopy (AAS) the sample has to be in the form of a solution. If the analysis is by OES using the point-to-plane technique, a solid surface of the correct size that has the proper surface preparation has to be available. Furthermore, if the gross sample or representative subsample is rendered homogeneous, it is much easier to obtain the final test sample. Procedures and equipment for improving homogeneity and rendering the sample suitable for particular methods of analyses will be discussed in section 3.

It should be remembered that the sampling and sample preparation procedures described and discussed in this chapter are intended only for the chemical analysis of metals and are not intended for the determination of physical properties such as hardness or tensile strength. The physical properties can change considerably during the discussed sampling and/or sample preparation procedures.

2 SAMPLING

When sampling different metals or metal products the objective is always the same: to obtain the sample that is representative of the lot. However, the methods and tools used to obtain this objective obviously cannot be the same for liquid molten steel, or a 25-mm diameter titanium bar, or a 5000-kg lot of nickel base alloy scrap consisting of machine shop turnings. In other words, the type, form, and origin of the metal to be sampled have a strong influence on the method of sampling. The principal forms of metal that are customarily sampled will be discussed below.

2.1 Molten Metals

2.1.1 Iron and Steel

Several procedures for steel and iron are discussed in detail in American Society for Testing and Materials (ASTM) Standard Practice E 1806, which discusses sampling procedures for liquid iron for steelmaking and pig iron production, liquid iron for cast iron production, and liquid steel for steel production. In pig or cast iron samples, it must be understood that the sample has to be chill-cast so the metallurgical structure will be suitable for spectroscopic analysis. Iron samples are generally cast into a coin or disk mold. Frequently these are combination molds in which one or more pin samples are attached that can be broken off later and used for thermal-type analyses such as carbon and sulfur determinations. A typical vertical mold is shown in Figure 1. A preheated steel spoon is filled with the molten iron by sampling from a stream or immersing in the melt. Any slag is removed and the liquid iron is poured into a cold mold without delay. It is important that the mold should be free from moisture.

Liquid iron and steel samples are frequently taken with probes. These fall into two categories, immersion sampling probes and stream sampling probes. Figure 2 shows typical immersion probes. Many of the probes are of the “disk and pin” variety, where the pin can easily be broken off and used for thermal analysis. These probes can be lowered into the melt manually or by mechanical means. Some of the probes also incorporate a thermocouple to take a temperature reading of the bath simultaneously. Figure 3 shows stream sampling and suction sampling probes. The probes frequently contain a deoxidant. There is one more type of probe, which is especially made for obtaining samples for hydrogen determinations. This type consists mostly of silica tubing mounted in cardboard tubing designed to produce pin or pencil samples 7–12 mm in diameter and up to 150 mm long.

2.1.2 Aluminum and Aluminum Alloys

Aluminum or aluminum alloys are cast most often into book molds, in which the sample disks are either in
METAL ANALYSIS, SAMPLING AND SAMPLE PREPARATION IN

Figure 3: Examples of (a) stream sampling and (b) suction sampling probes. (Reproduced by permission from ASTM (1997)).

Figure 4: (a) Vertical book mold and specimen. (Reproduced by permission of ASTM (1997)). (b) Vertical book mold. (Reproduced by permission of Angstrom Inc.)

Figure 5: Examples of (a) vertical (Figures 4a and b) or a horizontal position (Figure 5) when cast, depending on the mold type used. They both produce disks, usually 64 mm in diameter and 6–8 mm thick for the vertically cast disks and 6–13 mm thick for the horizontally cast disks. The advantage of the vertically cast disk is that a simpler and lighter mold is used and the 15–20 mm depression in the center makes machining easier and promotes a more uniform solidification. The disadvantage is that the area of excitation for the spectroscopic analysis is more limited. Generally, the two areas 90° from the sprue on the surface of the disk are to be used for the excitation. In the same way as the horizontally cast disk, the entire annular area can be used for excitation. The same size center depression in the horizontal mold also facilitates machining and promotes more uniform freezing. The disadvantage is that this mold is considerably heavier (3.5–4.5 kg). ASTM Standard Practice E 716 gives details of the sampling and sample preparation.
Figure 5 Horizontal mold and specimen. (Reproduced by permission of ASTM (1997).)

preparation of aluminum for spectrochemical analysis. For chemical analysis, samples can be obtained from the above described disks by taking drillings at areas that are also suitable for excitation.

2.1.3 Copper and Copper Alloys

Copper and copper alloys are generally sampled from the actual castings produced, or a disk sample is cast at the time the castings are made.

2.1.4 Zinc and Zinc Alloys

Zinc and zinc alloys are cast into the same types of mold as aluminum and aluminum alloys. ASTM E-634 specifies basically the same horizontal and vertical molds (see Figures 4a and b and Figure 5) as ASTM E 716. The procedures are also identical (see section 2.1.2).

2.2 Ingots, Billets, and Large Castings

The main difficulty in sampling these items is their large size. Most of the sampling will have to be performed with hand or portable tools. The other problem is that owing to their size the cooling (solidification) of the metal is gradual from the outside of the piece of the metal where it is in contact with the mold towards the inside. As this is generally a relatively slow process, a certain amount of “zone refining” takes place. The impurities or even some of the alloying elements tend to migrate towards the center, where the metal stays liquid for the longest time. The general rule is to take the sample at half radius. In most instances the sample is obtained by taking drillings from the large solids. Usually 12–25-mm diameter spade drills or twist drills are used, with the larger ones being preferred. For harder metals they should be carbide tipped. If the ingot or billet is saw cut into sections, it is an easy matter to take the sample from the half radius. However, if it is torch cut, the heat affected area caused by torch cutting should be avoided. Either the drilling should be sited in another area or the drilling taken from the first 4–5 cm should be discarded. Another possible drilling area is at the bottom of the pieces at the half radius, but, again, the drillings taken from the first 2–3 cm should be discarded. If the drilling is done from the side, the drillings should be discarded until the half radius is reached, making sample-taking quite a tedious job. It is always a good idea to check with those responsible for production before taking a sample, so that sampling location does not cause any great loss of material.

There are instances where drillings do not provide the best samples and small solids are preferable. Sampling of reactive metals (titanium, zirconium, hafnium) for the determination of gases is a good example. The best way to obtain these samples is to trepan the ingot with a hollow core drill specially made for this purpose. The metals should be appropriately cooled during the trepanning operation to prevent additional pick-up of gases, or loss of some gases in other metals. The loss of hydrogen in steel is a good example and, in that case, packing the area with dry ice together with a slow rate of drilling would be a good way to minimize this loss. The pins can be removed by breaking them off with the help of a screwdriver or a cold chisel. Hollow core drills resulting in a 6 mm diameter pin are most commonly used. In many instances these pins can also be used for spectroscopic analysis by OES, although a special sample holder might be required.

Metal ingots produced by consumable arc melting, plasma arc melting, electron beam melting or electroslag melting are generally not in a molten state in their entirety at the same time. This generally results in minor variations in the chemical composition along the length of the ingot. Major variations can even occur depending on the feedstock used. Metals produced by these processes should be sampled and analyzed in at least three places along the length of the ingot at the top, center, and bottom.

2.3 Mill Products

Extrusions, (such as I-beams, angle irons, small bars, and wire), rolled products, (such as bar products and sheet metal products) and tubing, (seamless or welded) all fall into this category. They may have various finishes, for instance, as-rolled or as-extruded, pickled, ground, polished, and so on. The lot of material may
come from one heating, or an unknown number of heatings and this information may or may not be available to the sampler, depending on who does the sampling.

Most mill products can be sampled in one of two ways. Either a small piece can be cut off the product from the end or drillings can be taken from the end. ASTM Standard Practice E 1806\(^2\) gives sampling positions for steel sections (see Figure 6). However, these locations can also be applied to other metals, since nonferrous sampling specifications generally are much less specific. A small slice cut off the end of a bar, extrusion, and so on, may be the preferred way, since in most cases, the slices lend themselves directly to spectroscopic analysis (particularly OES) after appropriate surface preparation. Special sample holders may be required. Many of the slices are also suitable for XRF analysis after appropriate machining is done to make them fit the sample holders. For slices that have small cross-sections, a longitudinal section will quite often be suitable.

2.4 Particulate Materials, Ores, and Minerals

Metal powders, shot, and uncompacted metal sponge, all fall into this category, as do friable metals, particularly ferroalloys that are highly friable and can readily be crushed (comminuted) to a small particle size. Ores, minerals, refractories, and slags may come in many sized chunks, but the large majority can readily be comminuted into small particles.

Some of these particulates may be fairly homogeneous while others, such as some ores and minerals, may be quite heterogeneous. The finer these particulates are crushed, the easier they are to mix into a homogeneous sample. However, this is only true to a certain limit. If the particle size is reduced below a certain point, the components separate. This sounds like an ideal situation as blending will then provide a homogeneous sample. However, when the constituents separate, particles of a different size, density, and shape are also obtained and these particles have a strong tendency to separate. For iron ores, ASTM Standard Practice E 877\(^5\) gives great detail on calculating the minimum sample size based on the nominal size and the specific gravity of the ore. For ferroalloys, ASTM Standard Practice E-32\(^6\) deals with the sampling of ferroalloys and steel additives. Basically, these are available either in lumps over 50 mm in size or in the form of crushed alloy (below 50 mm in size). The method of sampling depends on whether the material is shipped in bulk or in containers and on the type of the ferroalloy. More expensive ferroalloys, such as ferrovanadium, ferromolybdenum, ferrotungsten, ferrocolumbium, ferrotitanium, ferrozirconium, and ferroboron are generally treated differently from the cheaper ones, such as ferrosilicon, ferromanganese, ferrophosphorus, silicomanganese, and 12–15% zirconium alloy.

For the lower-priced group, one lump is taken for each 270 kg sample of bulk material, generally, while loading or unloading materials or, if the alloy is in containers, one container in five is dumped and one lump is taken for each 55 kg of material that was dumped (equal to one lump for each 270 kg of the total shipment). This is the gross sample. The gross sample is then crushed in a jaw crusher (see Figure 7) to pass a 6.5 mm screen and riffled to not less than 9 kg. This sample is then reduced to about 2500 g and reduced in size on a roll crusher to pass a 2 mm screen. From this 2-mm sample approximately 170–220 g is then pulverized on a ring pulverizer (see Figure 8) or hardened steel mortar and pestle to pass a # 100 (150 µm) sieve. The sample is dried at 105°C for an hour, and

![Figure 6 Sampling positions for steel sections: (a) billet or round, (b) slab, (c) angle, (d) channel, (e) tee, (f) and (g) beam, and (h) and (j) rail. (Reproduced by permission of ASTM (1997).\(^2\))](image-url)
divided by quartering if necessary. If the lot consists of crushed alloy, a 0.5% sample is taken during loading or unloading. This gross sample is crushed and pulverized as described above.

For the higher-priced ferroalloys, the procedure is basically the same except that all containers are emptied to form a cone-shaped pile. This pile is sampled by shoveling the pile of material. One shovelful of material from every three or four (depending on the size of the lot) is reserved as the gross sample. The sample is crushed as described above, except that larger portions are crushed during each step depending on the size of the lot. This is quite an elaborate procedure and is generally used for umpire analysis. For routine sampling, smaller samples are generally taken and not all containers are emptied. This procedure is a good example of a sampling process.

Reduction in sample size is mentioned a number of times. There are several simple ways to accomplish this task.

The first and simplest way may be by dumping the sample into a pile and transferring it into another pile by shoveling and placing every second, third, or fourth and so on shovelful into a sample container. The actual number will depend on the factor that the sample is to be reduced by. It should be noted that the more the sample is reduced by this method, the less accurate or representative it may become, depending on the heterogeneity of the material.

The second or “quartering” method is widely accepted. Here, again, the sample material is dumped into one pile and divided into four pie-shaped sections with a shovel (or a spatula, if the quantity is small and the quartering takes place on a benchtop). The four sections will be arbitrarily referred to as sections A, B, C, and D. Sections A and D are discarded (replaced in the original material) and sections B and C are blended together. This procedure is repeated until the blended sections B and C are of the size desired (see Figure 9).

The third method commonly used is the “splitting” or “riffling” method. This requires a sample splitter or riffle, a simple piece of apparatus (see Figure 10) also referred to as a Jones sampler, a Jones divider, a coal sampler, and so on. This unit basically consists of a large rectangular funnel that is divided into about a dozen narrow chutes. Each even chute conducts the material dumped on it to the left side of the splitter into a pan placed there, and each odd numbered chute dumps material to the right side of the splitter into a pan placed on that side of the chute. The chutes can normally be 10–50 mm wide, depending on the material that is being split. The sample that is to be reduced in size or split is dumped on the funnel with a special flat shovel that looks like a dustpan and is the full width of the sampler. Half of the sample will fall into each of the two sample pans. The contents of one of the two sample pans are discarded (replaced into the original material or reserved for potential resampling), while the contents of the other pan are dumped on the special flat shovel and split again. This is repeated until the desired sample size is reached.
2.5 Raw Materials

Raw materials can be defined as the material from which a product is made. In the metal industry the product is metal. The materials that go into the metal will depend on how integrated the particular producer is. A steel maker can start with iron ore, limestone, coal and so on and end up with pig iron. The pig iron can be converted into steel, in which case the additional raw materials may be alloying elements such as chromium, molybdenum, nickel (in elemental or ferroalloy form), and deoxidizers such as aluminum or titanium. Therefore, it can be seen that the raw materials of one producer may be the finished product of another producer. For this reason most raw materials used by the metal industry have already been discussed or will be discussed in other sections of this article. Ores, ferroalloys, and minerals are discussed in section 2.4. The alloying and deoxidizing metals, depending on what form they are used in, can be found in section 2.7 or if a ferroalloy is used, it is discussed in section 2.4. If new metal is used as an additive, it will probably fall into the category discussed in section 2.3 and sampling should be performed accordingly.

2.6 Finished Products

For the purpose of this discussion finished products will be considered to be metal parts products that have been produced for a specific application, such as a paper clip, screwdriver, chain, water faucet, turbine blade for a jet engine, or a fire extinguisher body. Generally these parts have to be analyzed either as a step in the final inspection (quality control), or as part of the incoming parts inspection program by the customer, or if problems arise with the part, in which case there may be litigation involved or at least contemplated. Fasteners, although they belong to this category, are regulated in the United States by federal law and have to be considered separately (see section 2.8).

For the purposes of the discussion in this chapter all nonmetallic parts, if any, will be disregarded. The sampling used has to depend on several factors:

- the reason for the inspection;
- the nature of the part, how critical the application is; how serious the consequences of failure of the part or product would be (with regard to loss of life or limb, property damage, or damage caused by downtime);
- the complexity of the specification;
- the past history.

If all these factors are considered it becomes evident that the reason for the inspection is a significant one, as the person performing a manufacturer’s final outgoing inspection has considerably more knowledge about the product than the person who performs the incoming inspection at the purchaser’s facility. The person performing the manufacturer’s final inspection has or should have knowledge about factors such as first, was the entire
lot product made from the same coil of material or the same heating of metal? Second, was the incoming raw material (metal) checked, and did it meet all specifications? Could any other parts that look similar have been mixed into the lot? Third, did the material exhibit any difficulty or unusual behavior during the manufacturing? First-hand knowledge of all of these factors can influence the size of the sample taken. This gives the advantage to the sampler performing the manufacturer’s final inspection. On the other hand, the sampler performing the customer’s inspection does not have this information and must assume the worst. The only information that may be available is the past history of the shipment made by the producer of the parts and whether the supplier has been used long enough to build up a reliable history. Sampling that is performed owing to a problem such as product failure and where there is or could be litigation involved, will be addressed in section 2.8.

If the second factor, the product itself, is considered, it is evident that, for example, a turbine blade that goes into an engine of a jumbo jet requires tighter quality control than a paper clip or a screwdriver. This translates into the need for a larger and more representative sample of the turbine blades.

Most of the items that fall into the category of finished products discussed here can be sampled in the same way as those in the solid mill products category (see section 2.3).

2.7 Scrap Metals and Metallic By-products

Sampling scrap metals and metallic by-products can represent special problems. First of all, many if not most of the scrap metal products are unique in the sense that they are only available and marketed as scrap items. Good examples are metal turnings, millings, drillings, or broachings that are generated as a by-product of their respective machining operations. Scrap metal is sold mainly to melters to lower the cost of the metal produced. Generally, normal sampling procedures, rules, and customs do not necessarily apply to scrap metal. On the other hand, no generally accepted published sampling standards for scrap metal sampling are available. Most of the time, scrap metal sampling is not only a science but also an art. A good scrap metal sampler has to have many years of experience, must be familiar with the scrap metal to be sampled, its history and origin, and has to be familiar with the intended end-use of the metal produced from the particular scrap metal to be able to do a good job. Regrettfully, little, if any reliable literature is available on this subject.

There are many types of scrap metal, turnings and millings, sheet metal scrap, small solids, mill scrap, fine residue type scrap, assemblies, baled and briquetted scrap, and “in-house” scrap. These types must be discussed separately.

2.7.1 Turnings and Millings

These originate from the machining operations of various metals. The turnings are drop-offs from a lathe or turning operation. The millings come from a milling operation. Most other machining operation scrap, such as boring from a boring mill operation, broaching from a broaching operation, drilling from a drill press, to name the more important ones, also fall into this category. Turnings represent probably the largest volume and can give the sampler the most problems. They are collected from the lathe operations in industrial plants and can represent any metal imaginable. Owing to their curly nature they are very tangled if purchased directly from the scrap generator (the manufacturing plant whose equipment generates the scrap) and do not lend themselves to normal sampling operations such as quartering, riffling, or just removing a handful. Turnings are generally a mixture of fine turnings from finishing operations. The larger heavier turnings are from first cut or roughing operations. There are two methods of sampling these turnings.

In the first method the entire lot of turnings can be crushed through a hammer mill (see Figure 11) or a ring crusher, and a sampling pipe is set in the stream coming from the output conveyor of the crusher, adjusted to collect about 0.1–0.2%. Turnings shipped by a scrap metal processor are generally already crushed.

The second method is faster and requires less equipment. However, it requires a more experienced sampler than the first method and is less accurate. The sampler has to estimate the proportion of the different types and sizes of turnings in the lot. He or she then hand picks a sample (possibly with the help of tin-snips) in approximately the same proportions as the lot, where the gross sample is

Figure 11 Hammer mill.
about 10–25 kg for a 5000 kg lot, passes this through a laboratory size hammer mill (run by a 3–4 kilowatt motor), and considers this to be the gross sample.

**Warning:** Some metal turnings such as magnesium, zirconium, hafnium, and titanium turnings, are highly flammable and can easily catch fire when crushed. Light magnesium turnings are not even sold as they are too flammable. Turnings are generally disposed of at the generation site by burning them under controlled conditions. However, the reactive metals can be crushed if proper precautions are taken:

- The crusher should be set up in an area well removed from all flammable materials, preferably out-of-doors.
- Crushing should always be performed under a constant and copious flow of water.
- The rate of crushing should be slow and even.
- Crushed turnings should not be left to accumulate at the output of the crusher, but removed continuously at frequent intervals.
- Zirconium and hafnium should only be crushed in small quantities in a small crusher.
- Appropriate fire-fighting equipment, in sufficient quantity, should always be available at the site of the operation.

There is one additional problem concerned with turnings and millings that has to be considered. When the turnings, millings, and so on, are generated, the machining generally is performed under a constant stream of cutting fluid to prevent overheating of the metal and/or to prolong the tool life. By the very nature of the cutting fluid, it adheres to the metals and much of it is retained in the shipment. Therefore, the bulk density of crushed turnings can be as low as 80–100 kg m\(^{-3}\). This may not be a negligible item, since when the buyer negotiates the price he or she pays for the metal. In some instances, a light metal such as light-cut titanium turnings or millings can contain as much as 40–50% by weight of water and cutting oils. This can practically double the price of the metal, if the oil and moisture (O&M) is not taken into consideration. The O&M contents can rapidly change.

2.7.2 Sheet Metal Scrap

Most of the sheet metal scrap consists of drop-off pieces from various manufacturing operations. They can be drop-offs from various shearing operations, or they can be the drop-offs from stamping operations. They can include rectangular cut pieces of various sizes, full size sheets, or ribbons of sheet metal with identical odd-shaped parts punched out of them and often referred to as skeleton scrap. Much of the sheet metal scrap that has been used in the aerospace industry (one of the largest generators of sheet metal scrap) is die marked with the grade of the metal, often stating the applicable ASTM or Aeronautical Material Specification (AMS) specification numbers. This can be a great help in evaluating the metal for uniformity.

The best way to take the actual sample is to remove small pieces from the sheet metal by shearing, nibbling, or clipping them with a pair of tin snips. If the lot to be sampled consists of several distinctive types, proportions should be estimated and the pieces sampled should be within those proportions. If the sample looks uniform to a person familiar with that type of scrap, a general sample should be taken from all areas of the lot. For best results the clippings, nibblings, or shearings should be melted into one solid homogeneous sample.

In some instances, the entire lot of sheet scrap is passed through a hammer mill and shredded into small, often postage stamp size, pieces. With this method much better sampling can be performed, particularly at the output conveyor of the hammer mill.
2.7.3 Small Solids

This can be either a very simple matter or a rather complex issue. Many small solids may consist of a lot of uniformly used jet engine turbine blades or small castings of identical parts with casting defects. These examples represent the simple cases. In these instances a simple plant scrap inspection method, as described in ASTM E 1916, such as inspection with a metal sorting spectroscope, a thermoelectric comparator, or a chemical-spot check can verify the uniformity of the material, so that a random sampling of the pieces will result in a good sample.

If the pieces are heterogeneous, the situation can be much more complex. For example, the lot can consist of used drill bits. A visual inspection may indicate that all or at least most of them are made of high-speed tool steel based on the HS marking on most of the drills. However, preliminary tests may indicate that they are a mixture of T-1 and M-2 grade steel, and the size or type of the drills is no indication of the steel grade. This leaves the sampler with two alternatives. Either the entire lot is segregated by an experienced scrap sorter using a grinding wheel and a simple spark test, and then a random sample is taken or a large random sample is taken and that sample is evaluated. The second method is obviously faster and less costly. However, depending on the results of the test, the product may still have to be segregated to make it acceptable for the melter. Another example of a more complex sampling problem is when a lot of material consists of used miscellaneous turbine blades, known to consist of only nickel and/or cobalt base alloy or alloys. A preliminary examination of the blades indicates that the lot consists of two nickel base alloys and one cobalt base alloy containing considerable amounts of tungsten (wolfram). Although the cobalt alloy blades are slightly different in shape, it is not possible to estimate the percentage of each alloy or to get a representative sample. Therefore, there again are two alternatives. First, using a metal spectroscope, an experienced scrap sorter can segregate as many as 5 to 12 pieces per minute. It may be more economically advantageous to segregate the entire lot by 100% sorting, than to take a random sample of the segregated portions to be melted and completely analyzed. In the alternative case, only one large sample is taken and the lot evaluation is based on this sample. This will give an average composition that can be of use only if the material is used as a refinery base, a relatively low value material. In other words, an evaluation has to be made to determine if any upgrading of the material should be done prior to sampling.

2.7.4 Mill Scrap

Mill scrap are larger pieces of scrap generated by the mill or primary metal producer, such as bar and/or billet crop ends, hot tops and so on. Generally these pieces of metal can weigh from 5 kg to 200–300 kg. Usually this kind of scrap, unless its history is reliable and known completely, is evaluated piece by piece using scrap sorting techniques previously discussed. A final sample can be taken by compositing drillings or millings taken from each larger individual piece, together with a random sampling of the smaller pieces. If different alloys are found by the sorting, each one is kept separate.

2.7.5 Fine Residue Scrap

The materials that fall into this category are grinding residues, bag-house dust from melting operations, and residues from pickling tanks. Practically all of these materials are intended for recovery of one or more metals. Generally, they do not represent major sampling problems except that, frequently, they are mixed with cutting and grinding compounds, water, oils and so on. The sampler has to be alert, as these materials frequently contain hazardous substances such as lead. These occur most frequently in bag-house dust. Appropriate safety equipment should be used when sampling such materials.

2.7.6 Assemblies

These are new or used manufactured products or parts that consist of more than one piece. They are fastened together by welding, glue, the use of fasteners, or by other mechanical means. Some assemblies contain only metallic parts made from the same alloy. Some can be made from an assortment of alloys. In other instances there are also nonmetallic parts such as insulators, O-rings, hoses, or plastic parts that may be included in an assembly. Assemblies can range from small electronic gold-plated circuit boards with at least some of the electronic components attached, to complete (or nearly complete) 2–3 m tall jet aircraft engines. Seldom do such assemblies get much further in the metal recycling chain than a scrap processor who specializes in such assemblies.

Such assemblies, particularly the more complex ones, cannot truly be sampled. Purchases of such assemblies are made on either a past experience basis, or on a purchase gamble by making a very low bid. This is particularly true if the lot consists of several assemblies that are all different. To obtain a good evaluation, the entire assembly has to be disassembled and the obtained components identified. To get a true picture, the disassembled components that have a value have to be sampled and evaluated (tested) individually. Particular attention has to be paid to contaminants that cannot easily be removed, for example, a small hose fitting that is silver-soldered to a nickel base alloy part.
2.7.7 Baled and Briquetted Scrap
Because many forms of scrap metals are bent, twisted, and curled to such an extent that the bulk density is considerably reduced, shipping and handling are very expensive. Consequently, many scrap processors compress such products in large presses. Sheet metal scrap is frequently compressed under considerable pressure into 30 × 30 × 45 cm bundles (the size can vary to a considerable extent), which are usually referred to as bundles, bales, or briquettes. Also, smaller often particulate-type scrap such as crushed turnings, millings and so on, is compressed into a shape resembling a large hockey puck. It can have a diameter normally ranging from 10–20 cm and can be about 7–10 cm thick. Such items are normally referred to as briquettes or sometimes as pucks.

These and sheet metal bundles in particular can represent a major sampling problem. The pucks made from turnings can generally be pried apart with a screwdriver and composites of samples taken from several pried-apart pucks resulting in a gross sample. However, compressed sheet metal bundles made of heavy gage sheet metal cannot be pried apart by ordinary means. Since the sheet metal is highly tangled in the bundles owing to the compression, it takes much more force to pull it apart than it took to make the bundles. The ideal solution is to take some random bundles, separately melt them and take a sample from the melt. This, however, in most facilities remains an unattainable utopia. Most of the time, taking clippings from the pieces that can be reached from the outside of the bundles is the best that can be done. Even this method is not simple if the sheet metal is heavy gage.

2.7.8 In-house Scrap
Scrap generated by the user is normally referred to as in-house scrap. If the user has a good housekeeping system and all scrap items are properly tagged and stored, many items only need some rapid alloy verification, if that, and do not need sampling. Other items that could become contaminated, such as machine shop turnings or broachings, can have a simpler sampling procedure performed during the pre-use processing. Results should be as expected, unless there is some breakdown in the system.

2.8 Special Considerations
There are several circumstances in which normal sampling practices do not apply. Some of these circumstances briefly discussed in this section are sampling and testing involved in shipments covered by buy–sell agreements or purchase orders, sampling and testing of certain fasteners, and cases involving litigation or potential litigation. These will be discussed here. However, laws and/or regulations change, so if any questions arise in these cases, for any other reason, the sampler and/or their company is strongly advised to seek competent legal advice.

2.8.1 Shipments Covered by Buy–Sell Agreements or Purchase Orders
When sampling is performed on a lot of materials that is covered by a buy–sell agreement or a purchase order, these documents sometimes specify testing and/or sampling procedures. In this case, the sampling and testing has to be performed as directed in the contract instead of in the customary way even if the customary way is an accepted sampling procedure. This may result in conflicts. For example, a lot of fasteners has to be sampled and tested in the United States according to a purchase order. The first thing to do is to establish if the fasteners involved are covered by the Fastener Quality Act (FQA) of 1990 (as modified), or not. If the fasteners are covered by the Act, any provisions of the purchase order specifying sampling or testing (including who shall perform the sampling and testing) are superceded by the law. Competent legal advice should be sought since the contract generally does not override the law. Another confusing situation that can arise is that the standard or specification cited in the contract does not contain the information called for. This is another instance that has to be resolved through commercial negotiations or legal channels prior to performing the sampling and testing.

2.8.2 Fasteners
The sampling and testing of critical end-use fasteners produced, sold, or used in the United States are regulated by the FQA of 1990. Basically, most metallic screws, nuts, bolts, and studs which have internal or external threads or load indicating washers with a nominal diameter of over 5 mm or 1/4 inch are covered under this law, if made to a standard specification which requires thorough hardening. In most cases, the inspection and testing, including the sampling on these fasteners has to be governed by the standards and specifications to which the manufacturer states that the fasteners have been manufactured. Testing laboratories have to be specially accredited by the National Institute of Standards and Technology (NIST), or NIST authorized accreditation bodies. The accreditations are based on International Organization for Standardization (ISO) Guide 25 and involve auditing the laboratory requesting accreditation by the accrediting body.
2.8.3 Cases Involving Litigation or Potential Litigation

If sampling and testing is due to a litigation (or a potential litigation), resulting from a shipment that did not meet, or allegedly did not meet, certain requirements of the purchase order or other agreement, or product failure resulting in monetary damages, injury, or loss of life, all sampling, sample preparation and testing has to be performed with extra care. All samples, potential samples, lots to be sampled or potentially to be sampled shall be immediately secured, preserved, marked, and identified, and, if possible, sealed to prevent tampering. One person should be put in charge of the technical aspect of the case, who should work closely with the company lawyer handling the litigation. Any sampling, sample preparation, and testing should only be performed with this lawyer’s approval, especially if the sampling, sample preparation, or testing is destructive in nature! Record keeping in particular should be discussed with the lawyer. No aspects of the case should be discussed with anyone else, including co-workers and superiors from the same company, except with the approval of the company lawyer. It should be understood that the opposing party may also be granted access to the sample(s) and possibly any or all records taken, including all notes and memos!

3 SAMPLE PREPARATION

Sample preparation deals with the procedures that result in a gross sample (or a representative portion of the gross sample) being rendered homogeneous and permitting a good laboratory sample to be taken which then can be prepared so that it is physically suitable for the analytical procedures that are to be performed.

For example, a lot of pure cobalt shot is to be analyzed that make up the gross sample. Brittle materials, such as ferrotitanium or silicon metal are best reduced in size to reduce the size of the gross sample to a laboratory size of large pieces or particles. This makes it impossible to individual particles. The gross sample frequently consists of ferro alloys, minerals, and ores. The answer is to reduce the size of the individual pieces or particles that make up the gross sample. Brittle materials, such as ferrotitanium or silicon metal are best reduced in size with the jaw crusher (see Figure 7). Jaw crushers are used in a gross sample (or a representative portion of the gross sample) being rendered homogeneous and permitting a laboratory sample for OES. One thin slice is chopped up on a shear to produce small pieces for the determination of carbon, sulfur, oxygen, and nitrogen. Chips are then removed from a slice and carefully collected on a mill or drill press. These chips are dissolved in acid (see Table 1), diluted to volume, and used for FAAS.

The sample preparation can be a long and rather complicated procedure. It can involve much more time than the actual analysis itself and may require considerable capital investment. The steps will be discussed in the order that they are performed:

1. sample comminution
2. sample melting
3. mechanical operations
4. dissolution and fusion.

3.1 Sample Comminution

When discussing comminution of the sample, it is understood to mean the reduction in the size of the individual particles. The gross sample frequently consists of large pieces or particles. This makes it impossible to reduce the size of the gross sample to a laboratory size sample and still maintain it as a representative sample of the lot. It should be remembered that the laboratory sample is frequently smaller than a single particle of the gross sample. This is particularly true of ferro alloys (or master alloys), minerals, and ores. The answer is to reduce the size of the individual pieces or particles that make up the gross sample. Brittle materials, such as ferrotitanium or silicon metal are best reduced in size with the jaw crusher (see Figure 7). Jaw crushers are used
extensively in the mineral and ore industry and by the master-alloy producers to reduce brittle lumps in size. They consist of a pair of heavy wear-resistant plates or jaws (see Figure 12) hammering at the material that is put between them until they are sufficiently reduced in size so they are able to pass between the two plates. The sample has to be passed through the jaw crusher several times. The distance between the jaws of the crusher is reduced each time the material is passed through the crusher. Jaw crushers can only be used with brittle materials and are not suitable for malleable materials such as aluminum, iron, and so on, or bulky materials such as machine shop turnings or light sheet metal scrap.

Comminution of malleable soft metals can pose a problem, especially if they are in a large solid form. Often there is no simple solution and the reduction of the gross sample size has to be accomplished without comminution of the gross sample, as was discussed in section 2.7.

^a^ One gram test portion is implied. Warm to complete reaction unless otherwise indicated. In most cases alternate dissolutions are possible. (Reproduced by permission of ASTM from Dulski (1996).)^10^  

Metal turnings and light sheet metal scrap can present another problem. Owing to their nature, these items can become entangled thus preventing any proper reduction in the sample size by quartering or any other simple method. Normally the best solution is to use a hammer mill (see Figure 2) to comminute samples of this type. Once their particle size is reduced, they will no longer become entangled and the sample size can be reduced by quartering or riffling. A hammer mill is a rotary crusher in which a series of hammers, sometimes also referred to as clappers, crush the material against a set of grate bars until the material can pass through the grates. Such jaw crushers have been used for many decades by the scrap metal industry and are very efficient. Both jaw crushers and hammer mills are available in pilot plant or laboratory size. When crushing samples in a hammer mill that are subject to oxidation, the crushing should always be performed under a copious stream of water. The cooling effect of the water will help to avoid, or at least considerably reduce, oxidation and in flammable metals will reduce the chance of a fire. The crushing of
highly flammable metals such as magnesium should be avoided.

Another way of reducing the size of the sample pieces or particles is by shearing them to size with shears which can range from large alligator shears (frequently used by the scrap industry), to small hand nibblers. This is again a labor-intensive method.

It should be remembered that whenever a sample is passed through a piece of equipment such as a jaw crusher or a hammer mill, the possibility of contamination of the sample is always present. The contamination can generally arise from three sources described below.

The first most frequent source is contamination from materials previously passed through the equipment. After finishing the crushing of one sample, a considerable amount of the material can remain in inaccessible places in the crushers, particularly in hammer mills. It is not sufficient to use an airstream to blow out the contaminants. The equipment has to be opened and completely cleaned out and inspected after each sample. Contamination from this source can be significant, particularly if the material processed in the equipment is of a different type than the next sample. When running more than one type of material through a piece of equipment, it may be advisable after type X material is finished and the equipment properly cleaned, to run a portion of the sample of type Y material through the equipment as a wash heat. Again properly clean the equipment and then process the actual sample of the type Y materials.

The second source of contamination can result from the crushing of metal samples. Critical construction parts of a crusher (the jaws of a jaw crusher and the hammers and grates or grate bars in a hammer mill) have to be made from the proper alloy.

Crushing operations generate a considerable amount of heat. Certain metals, such as reactive metals (titanium, zirconium and hafnium in particular) can pick up considerable amounts of gases owing to the heat. This third source of contamination, gas pickup, can be greatly reduced by running considerable amounts of water through the equipment during the crushing operation. In spite of these precautions, gas determinations should not be run on a sample that has been processed in a crusher unless the entire lot of material is similarly processed.

Warning: When crushing flammable metals such as reactive metals, magnesium and so on, a fire in the crusher is always a possibility even if water has been running through the crusher during the crushing operation. The equipment should be set up in an area where there are no flammable materials in the vicinity and where only small amounts of the flammable metal are close by, to minimize the size of the fire if it should occur. Operators should be trained in fire safety and fire-fighting procedures and there should be more than one person present at all times when operating and cleaning a crusher with flammable metals.

3.2 Sample Melting

The melting of a sample has a dual purpose. It renders the sample that is melted homogeneous and, at the same time, it puts it into a form that is suitable for many of the more commonly used analytical procedures such as OES and XRF. It also facilitates collection of the test sample for other analytical procedures. All melting procedures involve raising the temperature of the sample above its melting point, stirring the resulting liquid metal by some means to enhance its homogeneity, and finally cooling it in a suitable mold by a method in which the metal remains homogeneous.

Melting furnaces are classified by the way they generate the heat used to melt the metal. There are three types of furnaces in general use:

1. electric arc furnaces
2. induction furnaces
3. directly heated furnaces – these can be electrically heated or gas fired.

3.2.1 Arc Melting Furnaces

The laboratory-type arc melting furnaces (see Figure 13) consist of a water-cooled copper pot, which contains the sample to be melted. The copper pot and the metal sample which makes direct contact with it, act as the cathode, and a graphite or tungsten electrode is used as the anode. These components are enclosed in a tight enclosure that is provided with connections for vacuum and an inert gas, such as argon. A direct current electrical welder which has the capacity to supply 600 A acts as the power source for these furnaces. ASTM Standard Practices E 1010\(^{11}\) and E 1306\(^{12}\) discuss the apparatus and the melting procedures. In these furnaces, the melting pot also acts as the mold. These furnaces produce buttons up to about 36 mm in diameter that can weigh about 35–40 g for a titanium button or about 70–80 g for a steel or nickel alloy button.

These commercially produced laboratory arc melting furnaces are suitable for melting steel, iron, nickel alloys, cobalt alloys, reactive metals, or even smaller buttons of refractory metals. They are not suitable for melting aluminum and copper alloys, or generally low-melting-point alloys.

3.2.1.1 Advantages Arc melting furnaces are relatively low priced and economical to operate. They are the
3.2.1.2 Disadvantages

Owing to the high temperature of the electric arc, certain low-melting-point trace elements may be lost. Low-melting-point alloys, which include aluminum alloys, cannot be melted in these furnaces. The melts produced are relatively small and only what fits into the crucible can be melted as they do not have provision for making additions.

3.2.2 Induction Furnaces

An induction furnace consists of a refractory crucible surrounded by a water-cooled copper coil which induces heat in the metal charge of the crucible when the coil is connected to a high frequency power supply. The entire sample, when completely melted, is poured into a copper or iron ingot mold.

The entire assembly (crucible, coil, mold(s), pouring mechanism etc.) is enclosed in a chamber that can be evacuated and is used as a vacuum furnace or it can be backfilled with an inert gas such as argon and the melting can be done under a partial pressure of inert gas. Sample or alloying additions can be often made from one to several addition cups that are dumped onto a vibrating feeder that can feed the addition to the melt in the crucible at a controlled rate, and always under the control of the outside operator. Provisions for temperature measurement and bridge breakers for breaking up crusted tops can be incorporated as an option into these furnaces. Normally, laboratory-size vacuum induction furnaces (see Figure 14) are supplied with crucibles ranging from 5.5–13.5 kg steel capacity. Many furnaces are provided with a turntable within the chamber to accommodate several molds. The best molds are split molds machined from copper which produce a round ingot with a diameter of about 35 mm and a very large wall thickness in the range 25–35 mm to enhance rapid solidification of the sample.

The power supply frequency may vary depending on the manufacturer. However, it generally is in the 1000–10 000 Hz range for laboratory-size furnaces. The type of sample normally melted has to be considered, as lower frequencies have more penetrating power and are more suitable for melting larger chunks of metal, while higher frequencies have more of a “skin effect” and are more suitable for smaller thinner particles such as metal turnings. The coils used have to match the power supply.

Induction furnaces are generally suitable for melting steel, iron, nickel and nickel alloys, cobalt and cobalt...
alloys, aluminum alloys, copper alloys, rare earth metals, and so on. They are not suitable for melting reactive metals, because molten reactive metals attack the refractories of the crucibles, or for refractory metals, such as tungsten or molybdenum, because their melting temperature is generally too high.

Often if one attempts to melt light low bulk density samples in an induction furnace, there will be a problem for the metal to “couple” to the coil. This problem can be overcome by compacting the sample in a press and making small briquettes from the low bulk density metal.

Air-melt induction furnaces are not generally used in laboratories for sample melting, except in foundries or by metal producers who want to simulate their production furnaces.

3.2.2.1 Advantages The biggest advantage of the laboratory vacuum-induction melting furnace is that it is able to melt relatively large samples, which can considerably enhance the quality of the sample. It is also suitable for melting a wide range of metals. If the furnace is under an inert gas, such as an argon atmosphere, the loss of trace level tramp elements in aerospace alloys can be prevented.

3.2.2.2 Disadvantages Reactive metal samples cannot be melted in an induction furnace. A laboratory-size vacuum-induction furnace is a fairly high-priced piece of equipment costing perhaps 10 to 20 times as much as a laboratory are melting furnace. Melts are slow. It may take 1–2 h or more to produce a sample melt. Depending on the metal to be melted, a crucible may have a lifetime of 3 to 12 melts. Changing a crucible and drying it takes 18–24 h. It is considerably more difficult to clean a crucible properly after the melt in order to prevent cross-contamination from sample to sample. Ideally a separate furnace assembly (the coil, crucible, and the supporting box) should be available for each type of alloy melted to prevent cross-contamination. Changing these furnace assemblies between melts can also be time-consuming depending on the size of the crucible used.

The vacuum system requires extensive upkeep and maintenance to keep it in good operating order. An experienced operator is essential to produce proper uncontaminated samples and keep the equipment in proper condition.

3.2.3 Directly Heated Furnaces

Directly heated furnaces are the simplest of the three types of furnace discussed. They consist either of a crucible (carbon or refractory) heated by an electric heating element encased in a metal container and a lid, not unlike a small electric coffee pot, or of a crucible (carbon or refractory) supported in a refractory enclosure and heated by an air–gas flame. With the first type, which is also frequently used by jewelers, the molten metal is poured into the mold in a similar way as pouring from a coffee pot. With the second type the crucible is normally removed from the furnace with a pair of tongs, and with the help of the tongs, the melt is poured into the mold. These furnaces are used to melt precious metals (gold or silver), and generally low-melting alloys such as lead–tin alloys, aluminum, and so on.

3.2.3.1 Advantages These furnaces are very reasonably priced and require minimal maintenance. They are simple and fast to operate and do not require much special training to operate or maintain, with the exception of safety training. They are commercially available from stock.

3.2.3.2 Disadvantages They only operate as an “air-melt” furnace and in some instances fluxing is required to prevent oxidation. They only work with metal alloys that have a low melting point (actual top melting temperature depends on the unit).

3.3 Mechanical Operations

When a button or a small ingot is melted from the sample, or a slice is sawed off from a bar of steel, or a piece is cut off from a metal pipe, the pieces are not yet ready to analyze. They need additional preparation. Most of the preparation involves making sure that the sample piece is the right shape and the correct size and in many instances giving it an appropriate surface preparation. This can be achieved by a proper machine shop operation. An analytical laboratory, specializing in the analysis of metals will need a well equipped machine shop and should be equipped with a band saw, abrasive saw, bench top shear, mill, drill press, lathe, surface grinder (“swinging”-type preferred, see Figure 15), and a belt sander(s). Naturally the equipment depends on the work that the laboratory performs. A commercial testing laboratory specializing in metals in general may need all of the above equipment, while a laboratory serving only an aluminum foundry may only need a lathe and possibly a band saw for OES analysis, and perhaps a mill or a drill press if it also does wet chemical determinations.

It is not the object of this article to go into the operation details of all of the above-mentioned machinery. There are many excellent books written on the subject of machining various metals, such as one edited by Oberg. A fully equipped machine shop should be operated by a duly qualified machinist. Even if only one or two machine tools are required, they should only be operated by personnel fully familiar with the operation of the equipment. This is not only important to maintain quality, but also very important from a safety point of view.
The proper marking and remarking (should the original marking be destroyed in one of the mechanical operations) of all specimens cannot be emphasized enough. There are several good ways of marking specimens. They can be stamped with letter and number dies, engraved with a vibrating pen, engraved with an electric arc pen, and so on. Less desirable methods of marking samples are felt pens, as markings can be smudged by fingers (particularly oily fingers) or removed by solvents, labels can fall off and heavy specimens can also fall out of marked envelopes.

OES and XRF specimens have two basic requirements. First they must fit the sample holder of XRF spectrometers, or fit onto the arc or spark stand of the optical emission (OE) spectrometers, and second the surface on which the measurements are taken has to be flat and finished with an appropriate abrasive or machined in an appropriate way. If the specimens are melted in a laboratory furnace, the size is generally no problem. In button (arc) melting furnaces the size is normally not a problem, but one side of the button has to be machined flat. This is usually done on a swinging-type surface grinder, using an appropriate cup wheel, such as aluminum oxide. In the absence of this kind of grinder a lathe can be used, although the process is slower. A WC (tungsten carbide) tool bit is preferred. The final finish on the surface is done with a belt sander equipped with an appropriate belt.

When bars are cast in a laboratory furnace, the diameter of the bar is generally of the proper size and the bar only has to be sliced on a band saw. Sometimes an abrasive saw is required for harder metals. In most cases, high-speed tool steel blades are recommended for band saws. One of the surfaces again has to be prepared on a sander. Other round bar samples can be handled in the same way, but in some instances the diameter of the bar has to be reduced. This is generally best done on a lathe. With some solid samples, it may take a combination of machining steps to arrive at a suitable test specimen and the ingenuity of the machinist is put to a true test.

For the final surface preparation of XRF and OES analysis the usual way is to surface the specimens on a belt sander. The most common belts used for this purpose are alumina, silicon carbide, and zirconia. If the standard or procedure used specifies the grit size and abrasive used, it should be followed. If not, ASTM E 1257 can be used as a guide.

On disk specimens of softer (nonferrous) metals, such as aluminum, lead–tin alloys, and so on, the surface preparation has to be done with a lathe, as abrasive belts could cause smearing of the metal. When machining these surfaces, the automatic cross-feed on the lathe has to be engaged and very sharp tool bits must be used. It should be noted that the same feed rate has to be used each time on the cross-feed when machining specimens, otherwise the precision of the analyses will be affected. Precision also can be improved by the use of WC tool bits, because their sharpness is more constant and uniform than tools made from hand-ground tool steel.

Samples for wet chemical determinations are generally millings or drillings. They are obtained from solid specimens using a mill or a drill press. Sharp tools (mills or drill bits) have to be used, as dull tools do not cut, just burnish the metal and cause the sample to be contaminated. To prevent the drilling or milling from overheating, a coolant must be used. On vertically cast disk specimens, the drilling or milling should be done after the OES analysis is completed and the drilling should be taken from the same area. On horizontally cast specimens the drilling or drillings can be taken at any time. If taken before the OES analysis is done, the final surface preparation should take place after the drillings or millings are taken. The drill press table, mill table, (including any vise, clamps, hold-downs), drill bits, or mills should be cleaned very well before and after each specimen is machined to prevent any
cross-contamination. The drill bits and mills should be inspected after each specimen for any chipping or breakage. A chip from a tool bit can seriously contaminate a specimen and has to be recovered before the drillings or millings are ready for their intended usage. The drillings and/or millings have to be degreased because of the cutting compounds in the coolants used during the machining operation. Normally the degreasing/cleaning is done in a beaker with acetone. The beaker should be marked. The best way to mark it is with a pencil on the spot provided by the manufacturer for that purpose. Marking pens should not be used, as they can run and become completely illegible if the marking comes into contact with the acetone or acetone vapors. The dried chips should be stored in marked glass vials or in marked envelopes.

Sheet metal specimens are often very difficult to drill or mill. Small clippings or nibblings are often used instead of drillings or millings.

Small solids for thermal determinations have to be cut from larger pieces by shearing or by saw. The use of an abrasive saw should be avoided because of excessive heat. For metals that can pick up gases readily, the best solution is to use a manual hacksaw at a slow rate to avoid the pickup of gases. The surfaces should be slowly abraded with a file to remove any oxide layers. Reactive metal specimens should be given a light pickling in 1:2 HF: H₂O. For carbon determinations in cast irons, a solution of a particular metal can be prepared in two ways. It can be dissolved in an appropriate reagent at room temperature or at an elevated temperature. If the reagent is a liquid at room temperature, this operation is considered to be a dissolution and, as this reagent is nearly always an acid, it will be referred to as an acid dissolution. If the reagent is a solid at room temperature and has to be melted or fused at an elevated temperature to dissolve the metal, it will be referred to as a fusion. Naturally, the fusion itself must be dissolved in water or in a dilute acid to obtain a true aqueous solution. Therefore, the appropriate reagent for dissolution is generally an acid or a mixture of acids with possible additions. Fusions generally use molten salts or bases.

**Warning:** Before proceeding, it has to be noted that acid dissolution or fusion of metals deal most frequently with dangerous substances and elevated temperatures. Consequently, they should only be performed by people well versed in the technique or under the supervision of a person well versed in the technique, and only in a properly equipped laboratory. Appropriate personal safety equipment should be worn at all times even by experienced people. Particular care should be taken with hydrofluoric acid. Chemically this is a weak acid and contact with it does not cause immediate pain or any sensation. However, a throbbing pain may develop as much as an hour later by which time considerable nerve damage may have occurred.

### 3.4 Dissolution and Fusion

Many analytical procedures call for a liquid solution sample. They can be instrumental analyses or determinations such as AAS (both flame or flameless), or plasma emission spectroscopy (PES, direct current or inductively coupled) to name those used most frequently now in 1999, and all of the wet chemical procedures. The wet chemical procedures are particularly important, as many of these classical procedures constitute the bulk of the definitive methods. Their significance lies in the fact that they are based on stochiometric chemical reactions and do not depend on the simultaneous use of and comparison to reference materials with known analysis. Even today, if there are no appropriate reference materials available, definitive methods have to be used to perform the required determinations.

As most analytical methods frequently referred to as standards include the sample dissolution and/or fusion part of the sample preparations, this article will only deal with general procedures with respect to the preparation of the solutions.

A solution of a particular metal can be prepared in two ways. It can be dissolved in an appropriate reagent at room temperature or at an elevated temperature. If the
dissolution. Good examples would be (a) the loss of silicon and boron, when a sample is heated in the presence of hydrofluoric acid, (b) the loss of arsenic, when heated in hydrochloric acid without the presence of a considerable amount of nitric acid, and (c) the sudden volatilization of considerable amounts of chromium, when some hydrochloric acid is added to a fuming perchloric acid solution of a chromium-bearing alloy.

Another important factor is the rate of dissolution. Normally it is not practical to wait several days for a particular sample to dissolve. There are several factors that affect the rate of dissolution:

- the reagent mixture for the particular metal, considering not only the base metal (matrix) but also all constituents including possible contaminants;
- the sample shape and form. A particular concern is the surface-to-weight ratio. The larger the surface for a given weight of sample, the larger the surface on which the dissolution action (attack) can take place;
- the dissolution temperature; and
- any possible additions, such as a catalyst.

Let us look at these factors individually.

### 3.4.1.1 The reagent mixture

This may be the most important factor. Most published standard procedures state the method of dissolution, including all of the reagents to be used. This should be followed exactly. It is a very important part of the procedure and if the method of dissolution is not accurately followed, a claim for following the procedure cannot be made, as the method of dissolution can also affect the subsequent steps in the procedure. For procedures that do not specify the method of dissolution Dulski\(^{(10)}\) suggests the acid dissolution schemes for pure metals and metal alloys given in Tables 1 and 2.

### 3.4.1.1 The sample shape and form

When acid is poured on a metal sample, the acid can attack the metal only on the surface of the metal. If, for example, a \(0.25 \times 0.25 \times 0.25\) cm cube is cut from a larger block of steel, the cube will weigh about 1 g. The surface area, however, is only about 0.38 cm\(^2\). This is a very small area and it will take a very long time to dissolve the sample. If, however, drillings or millings are taken from the same solid sample and a 1 g sample is weighed out from these drillings or millings, the surface area will probably be several square centimeters for the 1 g sample, the actual

surface area depending on how heavy the drilling or milling cuts are. This gives the acids 5 to 20 times the surface area to attack simultaneously, and speeds up the dissolution process considerably. Another advantage of using drillings or millings is the fact that they generally take much less work and are easier to obtain than cutting off a small solid piece.

3.4.1.2 Temperature As in most chemical reactions, the rate of dissolution is enhanced at higher temperatures. Some dissolutions are sufficiently exothermic not to require additional heating. In some instances, the acid actually has to be added in increments to keep the reaction under control. This is particularly true when the metal particles are very fine and/or the surface area is very large. In other instances, the reaction is rather slow and additional heating has to be provided to keep the reaction going. There is also an added benefit of the heating. It provides some stirring of the reagent. When dissolution of a metal takes place there is evolution of a gas, generally hydrogen, nitrous oxides, and so on. These gases evolve at the metal–reagent interface. If there is no stirring involved, the gas bubbles just adhere to the metal surface at the interface and the reaction stops, or at least slows down considerably. The movement generated by the heat transfer from the bottom of the beaker and the increased gas generation keeps the solution sufficiently stirred so that fresh reagent solution permanently contacts the metal. The heat source should always be adjustable and under control. A continuously adjustable electric hot plate is preferred by many chemists. The rate of heating should be just sufficient to keep the reaction going at a good rate, while keeping evaporation of the reagent to a minimum. A watch-glass cover also helps prevent contamination by possible falling debris. In a few instances, elevated heat is necessary to dissolve the sample. This can be accomplished in an autoclave-like dish sometimes referred to as a “bomb”. It is usually a metallic (stainless steel) container that is lined with an inert plastic material such as Teflon™, which is suitable for the designed temperature, or a container made completely from a heat-resistant inert plastic. The stainless steel containers are heated in a conventional laboratory oven at a prescribed temperature for an empirically determined time. The containers made entirely from plastic are generally made to be used in specially designed microwave ovens, where the dissolution time can be considerably reduced. Adhering to the manufacturer’s given parameters is very important in the use of these methods. It is also very important to remember that the containers should never be opened before they reach room temperature. The pressure in these autoclaves also helps in the retention of volatile elements or compounds.

3.4.1.3 Microwave Ovens When discussing acid dissolution of samples, heating the samples was mentioned several times but only conventional hot plates and ovens were suggested as a source of heat. There is, however, a source of heat that has become popular since the early 1980s, namely laboratory microwave ovens (see Figure 16). These are actually very similar to the household units or those used by restaurants with some modifications. The modifications address the three problems of corrosion, safety, and convenience.

The problem in the corrosion area is obvious. Acids used to dissolve metals and metal-related substances are highly corrosive and so are the acid fumes generated during the dissolution process. Standard microwave ovens, with their electronic circuitry, are very sensitive to such a corrosive environment, particularly, since the electronic components and wiring are not hermetically sealed in the household and restaurant units. Modification consists in selecting the correct materials for construction and the appropriate methods of preventing the corrosive atmosphere from coming into contact with sensitive parts. The fumes can be eliminated or at least considerably reduced by dissolving the samples in sealed containers.

The question of safety is an important issue. Even if the corrosion problems are disregarded, much of the advantage of microwave ovens would be lost if the samples were placed in the ovens in an open or loosely covered vessel (beaker) as it is done on a hot plate. When a microwave oven is used, the samples are generally placed in sealed nonmetallic vessels that are capable of withstanding a limited amount of pressure, permitting a higher dissolution temperature without loss of volatile components. A microwave oven for closed vessels should at least have the capability of monitoring the pressure of each vessel as a safety measure. On many current units,
the pressure and temperature are monitored for each closed vessel and the unit will shut down automatically when a critical temperature or pressure is reached.

With respect to convenience, laboratory microwave ovens can be preprogrammed on a time–temperature or time–pressure basis.

The most important advantage of microwave oven acid dissolution is that there is considerable saving of time. In addition, samples that are very hard to dissolve such as high-carbon ferrochromium or chromium metal can be dissolved in a reasonable time. This time saving is particularly significant when a large number of identical samples, or samples that require identical programming of the oven have to be dissolved.

3.4.1.4 Additives In rare instances, the dissolution rate of a metal is very slow and a catalyst must be added to accelerate it. A good example is high-purity aluminum. If we try to dissolve it in dilute HCl, the reaction rate is so slow, as to be barely perceptible. The addition of one drop of metallic mercury will accelerate the dissolution to a reasonable rate. The mercury can be recovered after the dissolution is complete. Generally any special additives are specified in the procedures.

3.4.1.5 Acid Insolubles When the acid dissolution is completed, the reaction stops, sometimes leaving a small amount of dark-colored residue on the bottom of the beaker. The residue may or may not contain any of the analytes. As this is generally not known, the insoluble residue must be recovered. If a particular standard analytical procedure is followed, the procedure will tell the analyst how to proceed. If no procedure for the recovery of insoluble residues is given, they are usually recovered on a filter paper, washed, and ignited in a platinum crucible. If the retention of silicon is of no importance, a drop of dilute H₂SO₄ and a drop or two of HF are added to volatilize the silicon by carefully evaporating it to dryness and igniting the crucible at about 550°C. This is followed by fusing the residue, if any, in the platinum crucible with a small amount of flux (potassium pyrosulfate or sodium carbonate are frequently used). The cooled melt is then dissolved in a dilute acid and the solution is added to the filtrate. A guide for the selection of crucibles is given in Table 3.

3.4.1.6 Wet Ashing When there are organic materials or acid-insoluble particles present due to organic materials, there is a relatively simple method of removing the organic materials – the wet ashing procedure. The procedure basically consists of transferring the sample or the acid-insoluble residue that contains some organic material to a beaker and adding a quantity of concentrated nitric acid (not less than 30–50 mL) and 5–10 mL perchloric acid (70% HClO₄), then covering with a ribbed watch glass or a regular watch glass with glass hooks to separate the watch glass from the beaker. The beaker is placed on the hot plate and slowly heated. In the beginning, copious amounts of yellow nitric fumes will be emitted. When most of the nitric acid is evaporated, white fumes will start evolving. If the remaining solution starts to turn dark, it is a sign that there is still organic matter present and the beaker is immediately removed from the hot plate, left to cool slightly, more nitric acid is added and heating is resumed. When the solution no longer turns dark when the white fumes start to evolve, it is a sign that the organic matter has been decomposed and removed by oxidation. The heating is continued until the perchloric acid fumes are visible only in the upper part of the beaker. The beaker can be removed from the hot plate after 1 min of this fuming, cooled, and carefully diluted with water. This procedure must be carried out.

carefully and certain precautions have to be observed. (a) Only glass beakers, flasks, hooks, watch glasses, or stirring rods should be used when fuming with perchloric acid. (b) Sufficient nitric acid should always be present. If the solution starts to turn dark it should be removed from the hot plate immediately, cooled, and more nitric acid added. (c) A beaker should never be left on the hot plate unattended if it contains perchloric acid. (d) The operation should be performed only in a clean fume hood that has been designed for use with perchloric acid and this fume hood should not be used with any organic matter. (e) Only experienced analysts should perform this procedure and they should wear appropriate safety equipment, such as safety glasses or goggles, or preferably face shields. Any other personnel working in or close to the same hood should also wear similar safety equipment.

For wet ashing in a microwave oven, in which nitric–perchloric acid or nitric–sulfuric acid systems are to be used, the manufacturer of the equipment should be consulted to avoid any safety-related problems.

3.4.2 Molten Salt Fusions

When the acid dissolution for a metal, ore, or related material is not successful, the next step is to fuse the material with flux in a crucible and then dissolve the melt in dilute acid. This procedure is referred to as a fusion or molten salt fusion. It should be pointed out that these salts in the salt fluxes used in these fusions are not always salts in the pure chemical sense, but also contain substances such as NaOH or Na₂O₂. However, to simplify, they will be referred to in this article as salts and salt fluxes. The procedure is basically simple. The finely divided sample is placed in an appropriate crucible containing some of the salt flux and covered with the balance of the flux. It is mixed with a clean smooth glass rod and heated first at low temperatures to expel any potential moisture present and then slowly to high temperatures. Either a gas burner (the “Meker”-type is preferred), where the crucible is held on a tripod of appropriate size over the burner, or a muffle furnace is used. The crucible is covered with a lid of the same material. Frequently, the crucible containing the melt is swirled with a pair of tongs to facilitate completion of the fusion. When the fusion is completed, the melt is cooled to room temperature. The cooled melt is dissolved (leached) with an appropriate dilute acid or water that is later acidified. Again, appropriate safety precautions have to be taken and proper eye and face protection is essential.

If a standard procedure is followed, the crucible type and material are specified; if not refer to Table 3. Generally the sample size, flux, and flux quantity are also specified. These should be followed closely. If no procedure is found or no fluxes are suggested, fluxes suggested by Dulski[10] can be used as a good starting point (see Table 4).

A few words about crucibles. The most common crucibles are made from porcelain, fused silica (quartz), iron, nickel, platinum, and zirconium. Today, the platinum and zirconium and, in certain fusions, fused silica crucibles are most frequently used, although owing to the high price of platinum and zirconium crucibles, nickel or iron crucibles can be substituted, resulting in a shorter crucible life and potential for greater contamination by the crucible material. Normal crucible sizes used range from 25–40 mL.

3.4.2.1 Beads for X-ray Fluorescence Spectrometry Analysis A special application of molten salt fusions is the preparation of buttons, often referred to as beads, for direct analysis by XRF. The principal use of buttons is for samples where XRF analysis is desirable and there are difficulties in obtaining a suitable metallic specimen owing to various reasons such as the brittle nature of the metal, difficulties in remelting the sample without affecting the composition, and so on. A good example is ferrotitanium.
The samples are generally pulverized and a representative portion of the pulverized sample is fused with an appropriate salt or salt mixture. The fusion is most often performed in a heavy platinum or platinum–gold alloy crucible and the fusion is cast into an appropriate mold. The glass-like buttons or beads are then analyzed by XRF in the usual way, using analytical curves established with beads prepared from reference materials in the same way as the samples. Lithium metaborate, lithium tetraborate, sodium tetraborate (borax), and boric acid are among the most frequently used salts for this application.

This article examines contemporary routine and umpire quality methods for the analysis of nickel ores, nickel metal and nickel alloys. Sample preparation and sampling are also discussed, but the emphasis is on sample preparation and analysis, since sampling is all too often done by people not part of the analytical laboratory.

In order to analyze fully these materials, a laboratory must have at its disposal a wide range of instruments and methods, from the classical to the most modern, and frequently combinations of both. In keeping with the theme of this Encyclopedia, detailed methods are not given, and the reader should consult the references. The references themselves cover the period from roughly 1972 through 1997 but are not to be considered a definitive list. Unfortunately, most of the modern methods of analysis developed by chemists in nickel producers' laboratories have not been published, except as international or national standards. As an aid to the reader, a summary of International Organization for Standardization (ISO) and national standards is given immediately before the References. The author apologizes for any errors or omissions.

The section on nickel ores is divided into two broad classifications: sulfide and lateritic ores. Greater emphasis is given to the sample preparation of laterites since they are more difficult to handle and many laboratories do not have as much experience working with them as with sulfides. Each broad classification is broken down into the analysis of “pay metals”, which are the reason the ore is mined, elements of environmental concern and other elements which are required for the metallurgical processing of the ore.

Products from refineries fall into three broad categories: nickel metal in various forms, nickel oxides and ferronickel. For nickel metal, the emphasis is on trace-element determinations; for nickel oxides and ferronickel, methods for the determination of nickel are also discussed.

Nickel alloys cover a wide range of materials, from stainless steels to high-nickel “superalloys”. For these samples the analytical requirements range from the major components of the alloy to minor alloying constituents to trace-element determinations.

As an aid to the analytical chemist in the laboratory, tables are presented summarizing recommended methods of analysis, and in most instances an alternative method, in case the laboratory does not have the equipment necessary to select the first choice. These methods have proven themselves in the laboratories of nickel producers and commercial laboratories familiar with the analysis of nickel-bearing samples.
1 INTRODUCTION

For a general overview of the early development of the nickel industry and the analytical chemistry associated with it, the reader should consult The Analysis of Nickel\(^1\), Analytical Chemistry of Nickel\(^2\) and two volumes in the series prepared by the Vernadskii Institute on the Analytical Chemistry of the Elements, Analytical Chemistry of Nickel\(^3\) and Analytical Chemistry of Cobalt.\(^4\) All of these books were written in the late 1960s.

Nickel is a transition-metal element and is closely associated with iron, cobalt and the platinum metals. The main use (about 65% of consumption) for nickel is as an alloying element in stainless steels, where the addition of nickel and chromium imparts greater corrosion resistance. High (35%) nickel, chromium and iron alloys are also used in petroleum refineries owing to their corrosion resistance and thermal resistance. Other important uses are in jet engine “superalloys”, where the ability to withstand high temperatures is critical. In these alloys, nickel is the major constituent (>60%). Superalloy manufacturers demand very high-purity nickel and place severe restrictions on trace-element concentrations. The platining industry is also a major consumer of nickel, particularly for automobile components. A growing use for nickel is in batteries. Nickel–cadmium (NiCad) batteries have been in use for many years. A potential, but not yet commercial, use is for battery-powered vehicles. Many countries use nickel in coinage, often produced from nickel powder. Nickel powder is also used in powder metallurgical applications. Nickel is also used in catalysts.

Cobalt is used as an alloying element in high-temperature alloys and in high-strength magnets, e.g. cobalt–samarium magnets.

The platinum-group metals are most often used industrially as catalysts, and there is some use in jewelry.

The analysis of nickel ores and metals poses a number of unique problems for the analytical chemist. In ores, nickel is usually a minor component (1–10% by weight), and is often associated with other pay metals such as copper, cobalt, gold, silver and the platinum-group metals. In refined nickel metal, nickel itself is not determined directly. Rather, the trace impurities are determined, and the nickel content is estimated by difference. The trace impurities are of particular interest to superalloy manufacturers, since small amounts of some elements (Pb, Bi, Se, Te and Tl especially) can segregate to crystal boundaries, causing structural weaknesses in turbine blades.

In ferronickel, the two major components are iron and nickel. Nickel is determined, since the material is bought and sold on the basis of nickel content. Usually various minor and trace impurities are also determined. The principal market for ferronickel is the stainless-steel industry.

Some smelters produce nickel oxides as their final product. Some are fairly pure and are often destined for chemical manufacturers. Others are much less pure, almost an intermediate product containing considerable amounts of gangue material, and are sold either for further refining or to low-alloy steel producers. Nickel is determined in these oxides in addition to whatever other elements are deemed important for the end-use of the oxide.

In ores, several components besides the pay metals are also determined. Elements such as sulfur, silicon, magnesium, lead, arsenic, bismuth, selenium and zinc are of metallurgical and/or environmental interest.

Nickel ores occur as three broad types: sulfides, silicates and nickelifereous iron ores (laterites). There are other types, such as arsenides, but these are of relatively little importance. Sulfides, containing nickel mainly as pentlandite, a nickel–iron sulfide, account for about 30% of the world land-based nickel resources. Economically recoverable amounts of cobalt, copper, gold, silver and the platinum group metals are often associated with the nickel sulfide minerals. For the purposes of this article, silicates (saproilites) and nickelifereous iron ores (limonites) will be discussed under the broad term “laterite”, since they can be analyzed in a similar fashion. The only additional by-product from laterites is cobalt, which may be present in sufficient quantities to justify its recovery. Of potential interest in the distant future are “manganese nodules” found on the ocean floor. As yet no way has been found to harvest these nodules in an environmentally safe and economic way. For more on nodules, see Haynes and Magyar.\(^5\)

Nickel deposits are found widely throughout the world. Sulfides are found primarily in the Russian Federation (29%), Canada (26%), Australia (14%), China (11%) and Africa (13%). Nickel laterites (a weathered, clay-like material) are found mainly in the tropics. The laterite deposits are found near the surface in the Caribbean (Cuba, Dominican Republic, totaling 25%), New Caledonia (20%) Indonesia (16%), the Philippines (11%), Australia, (8%), Africa (8%) and Central and South America (8%). Minor amounts are found in the Balkans and in Greece.

In 1998, sulfides accounted for 53% of the worldwide production of about one million metric tonnes (10^6 t). This percentage is lower than in the 1960s when sulfides accounted for 75% of nickel produced. Most of the sulfide deposits are well below the surface, although there is a major near-surface deposit, yet to be developed, in the Voisey’s Bay area in Labrador, Canada.

The production of nickel metal from ores involves several steps. For sulfides, the ore is crushed, then usually...
put through concentration steps (froth flotation and magnetic separation) to separate metal-bearing minerals from as much of the gangue (usually silicates) as possible. The concentrate, upgraded 4–15 times from the ore, is then treated pyrometallurgically (roasting, smelting and converting) or by a flash smelting process to form a matte. The matte is treated by further flotation separation, matte refining processes or hydrometallurgical processes. Refining to produce nickel metal is done by electrolytic methods or by the nickel carboxyl process.

Laterites cannot be upgraded to the same degree as sulfides. After the removal of low-grade rocks, the ore is dried and may be smelted directly to produce ferronickel. Other processes involve smelting with gypsum (Société Anonyme le Nickel in New Caledonia) or with high-sulfur oil plus elemental S (Inco Indonesia) to produce matte which is then shipped to a refinery. Shipping a matte is much more economic than shipping an ore or a concentrate. However, with improved hydrometallurgical techniques, using either ammonia or acid leaching, laterites are becoming more and more economically attractive to mine and process than sulfides, particularly since mining costs are significantly lower.

The major miners/producers of nickel are Inco, Falconbridge and Sherritt (the last company receives most of its feed from Cuba at time of writing) in Canada, Outokumpu in Finland, Société Anonyme le Nickel in France (with feed from New Caledonia), Norilsk, Montschegorsk and Razno in Russia and Western Mining and Queensland Nickel Industries in Australia. Inco also has a large operation in Indonesia and Falconbridge has a significant ferronickel operation in the Dominican Republic. Lesser miners/producers include Toctantins and Codemin (Brazil), Cerro Matoso (Columbia), Matthey Rustenburg, Empress Nickel, Bindura and Impala (Southern Africa), Aneka Tambang (Indonesia), Larco (Greece), Kosovo (Yugoslavia), and Jinchuan (China). The Japanese have no mines, but there is some refining of matte in that country by Sumitomo, Pacific Metals, Nippon Yakin and Tokyo Nickel. Taiwan Nickel Refining produces utility nickel, a lower-grade product used in the making of low-alloy steels. Glenbrooke in the USA produced ferronickel, but has ceased production at time of writing. Cubaniquel in Cuba produces nickel oxide sinters.

This article will examine contemporary routine and umpire quality methods of analysis for nickel ores, nickel metal and nickel alloys.

2 HISTORY

Prior to the introduction of atomic absorption spectroscopy (AAS) into the analytical laboratory, nickel ores and metals were analyzed by tedious separation, gravimetric, titrimetric and spectrophotometric methods in the wet analytical laboratory and by X-ray fluorescence (XRF) spectroscopy. Flame atomic absorption spectroscopy (FAAS) and its companion, electrothermal atomic absorption spectroscopy (ETAS) have enabled the analyst to determine most of the elements required for the analysis of ores and metals, from macro to micro concentrations. As a result, the use of the “classical” techniques of separation and spectrophotometry are rarely, if ever, encountered now, although a recent paper described the spectrophotometric determination of Co sample.

Classical wet chemistry still finds a place in the analysis of standard reference materials (SRMs), and in settlement or umpire analysis. In recent years, inductively coupled plasma optical emission spectroscopy (ICP-OES) has come into wide spread use, supplanting AAS in many laboratories. Most recently, inductively coupled plasma mass spectrometry (ICP-MS) has been introduced, primarily for the determination of trace impurities. Recent advances in FAAS such as flow injection hydride generation and multi-lamp configurations coupled with computerized data retrieval have allowed this technique to become more competitive with ICP-OES.

Nonmetallic elements of interest (carbon, sulfur, oxygen, nitrogen and hydrogen) are still commonly determined by combustion and fusion techniques. Here the major advances have been in furnace design and detection systems, but the basic technique has remained the same.

Refined nickel metal is produced in a number of grades of purity. These grades used to be defined in terms of nickel plus cobalt content. Today, refining methods permit much better separation and recovery of cobalt, and the current ISO standard 6283 regarding impurity limits for various grades of nickel refers to nickel content and not to nickel plus cobalt. American Society for Testing and Materials (ASTM) B39 is another widely used standard (e.g. used by the London Metal Exchange) for grading refined nickel. The British Standard (BS) 375 and the German specification Deutsche Institut für Normung (DIN) 1701 are also widely respected.

3 ANALYSIS OF NICKEL ORES

3.1 General Sample Preparation and Preservation

Drill core should be split before crushing, the uncrushed half being retained as a record and/or back-up in case samples are lost in transit from the drill site to the laboratory. The retention of half the core as a record for future inspection and verification of laboratory results also serves to help protect investors from fraudulent
mining promotions. Ore from a mine should be sampled using proper sampling methods, if the laboratory results are to be used for process metal balances. The size of the ore pieces may range from powder to 0.5 m.

Sulfide ores are generally hard. Laterites are soft, particularly near the surface where they are weathered, and these can often be split with a knife. As the depth of the laterite deposit increases, the ore becomes less weathered and consequently harder, especially if olivine is present.

In general, the bulk sample is crushed through various steps to smaller and smaller pieces. During the crushing stages, the sample size is reduced by half to one quarter at each step. A portion of the reject from each crushing step should be retained in case contamination occurs at a later step. The crushing continues until the sample has been reduced to about 10 mesh in size. A representative portion, about 200 g, is then pulverized to −100 to −200 mesh, usually in a ring and puck type of pulverizer. This sample is then placed in a suitable container and sent to the laboratory for analysis. If more than one laboratory is to conduct analyses, then the amount pulverized should be increased accordingly. There are concerns specific to the preparation and preservation of sulfides and laterites which are given below.

For laterites, the ore should be dried at 100°C for 1–2 h (depending on the ore), and then crushed with a jaw crusher while hot to avoid gumming up the crusher. Moisture pick-up by laterites is a major concern and is dealt with in detail below (section 3.3.1).

Cross-contamination can occur during crushing if the equipment is not cleaned between samples. In practice, for exploration samples, the core is usually of similar grade and this cross-contamination is not too critical, and minimal cleaning such as a burst of compressed air is sufficient. For more critical samples, a barren mineral such as sand or nephelite silica is often used in addition to compressed air. For extremely critical samples, a small amount of the actual sample may be passed through the sample preparation stream to reduce any slight contamination from remnants of the cleaning material (sand).

3.1.1 Nickel Sulfide Ores

Care must be taken at the pulverizing step. The friction of the moving components of the equipment (such as ring and puck) in contact with the ores can lead to a heat buildup. When the powdered ore is dumped on to a sheet of paper, the sulfides may react with the oxygen in the air and become hot enough to ignite the paper. This problem is common to all sulfide ores, and sample preparation personnel should be made aware of this possibility. Often there is a smell of SO₂, indicating that oxidation is occurring. The pot should be placed in a small can, a lid put on and allowed to cool before opening the pot.

The sample should be packaged quickly to minimize oxidation of the sulfides. After the analysis, the sample should be stored in a sealed container and/or in a freezer to prevent oxidation from occurring. Storage under nitrogen has been used for certified reference materials. All samples and rejects must be properly labeled.

3.1.2 Nickel Laterite Ores

Laterite ores present problems for the sample preparation laboratory. They are very similar to clays, and are extremely hygroscopic. This often results in smearing and caking, particularly in the pulverizing step. The best way to prepare nickel laterites is to moisten the crushed ore with a small amount of alcohol (methanol or ethanol). The alcohol absorbs moisture in the ore and prevents caking during pulverizing.

The pulverizing equipment, usually a steel ring and puck in a pot, must be well cleaned after each sample is ground. Greater care than normal is required owing to the clay-like material sticking to the surfaces.

Once pulverized, the samples are prone to gain weight by absorbing moisture from the air. Drying the sample at 105°C and storing it in a desiccator will give inaccurate results. The ore is so hygroscopic that it will absorb moisture even from fresh desiccator. For routine analysis, the ore should be stored in an oven at 105°C until the sample is to be weighed.

The best way to obtain an accurate analysis is to weigh two portions of the pulverized sample, one for the elemental analysis and the other portion for moisture, and correct to a dry weight basis. Because this is critical, the determination of the moisture content is described in some detail below (section 3.3.1).

The pulverized samples are relatively stable with the exception of moisture pick-up.

3.2 Analysis of Nickel Sulfide Ores

3.2.1 Pay Metals (Nickel, Copper, Cobalt, Gold, Silver, Platinum Group)

3.2.1.1 Determination of Nickel, Copper and Cobalt by Wet Chemical Methods

By Dissolution with Mineral Acids. A common method is to attack the sample (usually 1 g) with 1:1 hydrochloric acid and heating on a hot-plate. This has the advantage of converting the sulfide sulfur to the volatile H₂S, reducing the amount of dissolved solids. When dissolution ceases, the insoluble matter is filtered,
ignited and fused with sodium peroxide in a zirconium crucible in order to achieve the complete dissolution of the sample. The filtrate contains most of the base metals as well as others of interest (see section 3.4). The sodium peroxide melt is dissolved in water and acidified with hydrochloric acid. The fusion solution will contain small amounts of Ni, Cu and Co which can be occluded in the crystal lattice of silicates or as impurities in refractory minerals such as magnetite which is often found in the Sudbury ores. It is best not to combine the two solutions, but to dilute each to an appropriate volume for analysis by classical wet chemistry or by FAAS or ICPOES.

Inco developed a method for the microwave acid digestion of sulfides, followed by FAAS.\(^9\) This procedure has been supplanted by fusion with sodium peroxide in a zirconium crucible followed by acid dissolution of the melt.\(^9,10\) The latter procedure is currently in routine use in Inco laboratories.

A simple method for acid dissolution where only Cu, Ni, Co and Fe are to be determined is the four-acid method. A 1-g sample is heated in a glass beaker with concentrated HCl to decompose most of the sulfides. A few milliliters of HNO\(_3\) are added, then a few drops of HF (caution) to break up silicates, then a few milliliters of H\(_2\)SO\(_4\) are carefully added and the sample is heated gently to dryness. The sample is taken up with a few milliliters of 1:1 HCl and some water and heated to complete dissolution. After dilution to an appropriate volume, the sample is analyzed by FAAS or ICPOES. Perchloric acid (caution) can be used instead of sulfuric acid. The method can be applied to both sulfides and laterites.

If the determination of Ni is to be done by the classical gravimetric determination by precipitation with dimethylglyoxime (DMG) (see the next section), it is best to heat the sample solution to strong fumes of perchloric acid to dehydrate silica. This is necessary to prevent falsely high results owing to SiO\(_2\) being occluded in the NiDMG precipitate.

**Caution:** Perchloric acid must only be used in a fume hood specifically designed to withstand perchloric fumes. The use of regular fume hoods has resulted in major explosions in laboratories.

**Determination of Nickel by Classical Wet Chemistry.** The determination of Ni by precipitation with DMG has been described in many undergraduate textbooks. For sulfide ores, an aliquot of the solution from section 3.2.1.1 containing 25–50 mg of Ni should be taken. Tartaric acid must be added to complex Fe, which is always present in large amounts. Sodium thiosulfate must also be added to complex Cu. The weight of Na\(_2\)S\(_2\)O\(_3\)·5H\(_2\)O should be 15 times the weight of Cu plus Fe, with a minimum of 3 g. The salt is usually added as a 20% w/v solution, and 20 ml is commonly used. Alternatively, the Cu may be removed and determined by electrolytic plating prior to the precipitation of Ni with DMG. The NiDMG precipitate may be filtered through a tared sintered-glass crucible, washed carefully with water and dried at 150 °C. The drying temperature is critical. It must be high enough to dry the precipitate and to volatilize any residual DMG, but not high enough to decompose the NiDMG precipitate. The crucible is then weighed and the percent nickel is calculated.

An alternative is to filter the NiDMG precipitate through a fast filter, wet ash the paper and precipitate and titrate with ethylenediaminetetraacetic acid (EDTA) using murexide as the indicator. This alternative is faster and avoids the risk of incorrect results owing to improper drying of the precipitate.

The DMG precipitation procedures are generally restricted to umpire analysis or SRMs certification.

Xiang et al. reported the potentiometric determination of Ni and Cu.\(^{11}\)

**Determination by Flame Atomic Absorption Spectroscopy or Inductively Coupled Plasma Optical Emission Spectroscopy.** For FAAS and ICPOES it is imperative that the analysis be carried out using matrix-matched standards. The filtrate solution from dissolution with mineral acids (see above) is usually fairly stable, but if older than a few days it should be inspected for any precipitate which may have appeared. Any such precipitate is unlikely to contain enough Ni, Cu or Co to affect the accuracy of their determination. The insoluble sodium peroxide fusion solution is much less stable, particularly if the sample contains large amounts of silica and/or alumina. It is best to analyze this solution as quickly as possible.

Another approach, developed by Inco,\(^{9,10}\) is to fuse the sample with sodium peroxide in a zirconium crucible. For large production runs, an automatic sample fluxer is employed. The melt is then dissolved in water, acidified with hydrochloric acid, diluted to an appropriate volume and analyzed by ICPOES against matrix-matched standards. This procedure retains the sulfur, which is oxidized to sulfate by the sodium peroxide, and the total sulfur is also determined by ICPOES. This procedure is in routine use at Inco laboratories.

**Caution:** Sodium peroxide is a very strong oxidant. Sulfide is a strong reductant. Heating the two together can produce a violent reaction unless great care is taken.

Claise\(^{12}\) indicates that Ni sulfides can be fused in platinum crucibles if the sample weight is kept to a maximum of 0.25 g, and an oxidant such as LiNO\(_3\) (to convert sulfides to sulfates) is used with the Li or Na tetraborate flux. Exceeding this sample weight may cause an alloy to form with the platinum crucible. LiBr is used as the releasing agent in place of the usual iodide owing
to the volatility of copper iodide. The melt may be poured into a dish to form a glassy disk for XRF analysis, or be dissolved in a suitable acid such as 10% v/v nitric acid for ICP-OES analysis (see Claissen, (12) p. 44).

3.2.1.2 Determination of Nickel, Copper and Cobalt by X-ray Fluorescence Spectroscopy This technique has been used by analytical laboratories for almost 50 years to provide rapid and accurate results. Improvements in the hardware and, more important, in the software, have helped this technique withstand the challenges of FAAS and, more recently, ICP-OES.

These metals can be determined fairly accurately by fusing a 0.2-g sample with 5 g of potassium pyrosulfate in a quartz crucible. The fusion homogenizes the sample, breaking up the various mineral species, and the potassium pyrosulfate dilutes the sample, reducing matrix effects. The fusion also oxidizes the sulfides to sulfates. The melt is ground finely in a porcelain mortar and pestle, then is briquetted in a mounting press for analysis. The XRF spectrometer may be calibrated using a variety of reference materials including pure metals, as long as they fuse completely with the pyrosulfate. If these are not commercially available, a suite of samples covering the expected concentration ranges must be analyzed carefully by wet chemical methods, in order to serve as in-house secondary standards. The briquette is stable almost indefinitely.

This general procedure has been used with confidence for many years at Lakefield Research Limited (13) and can be used for metal balances. XRF has been used elsewhere. (14)

The pressed powder technique, where the pulverized ore is mixed with a suitable binder and is pressed into a smooth, flat disk under very high pressure, is a powerful technique for the rapid analysis of exploration and mine development samples. Several hundred samples per day can be analyzed. The instrument is calibrated using secondary standards of the ore, carefully analyzed by wet chemical methods. These calibration curves are, however, dependent on the mineralogy of the ore. If samples from a different ore zone or ore body are submitted for analysis, additional secondary standards and calibration curves must be developed.

The use of XRF is not restricted to the analytical laboratory. On-stream analyzers (15) located in mills and flotation circuits are valuable tools to plant operators. These analyzers are best calibrated by personnel from the XRF analytical laboratory, who have first selected appropriate samples for calibration, and have derived the correction factors to be used. This method is applicable to both sulfide and laterite samples. Caution must be taken with the storage of laterite disks, since they can pick up moisture, easily swell and distort the geometry of the disk.

On-site XRF spectrometers can also speed up the assessment of exploration samples and ore samples. (16)

3.2.1.3 Miscellaneous Techniques γ-Ray spectrometry has been used for bulk ore analysis. (17, 18)

3.2.1.4 Determination of Silver, Gold, and the Platinum Group Metals by Fire Assay Au, Pt and Pd are usually determined by the classical fire assay with lead collection, adding a small amount of silver to give the final bead enough size to be handled easily (a silver inquart). The fire assayer will experiment with the ore to determine the best fusion flux for that particular ore. After fusion and cupellation of the lead button, the silver bead containing the Au, Pt and Pd is dissolved in aqua regia and the metals are determined by ICP-OES (19) or FAAS. This general procedure is in common use in most commercial assay laboratories. For a general text on fire assaying, see Bugbee (20) and Dietrich and Shepard. (21) For more detailed information of the chemistry of precious metals, see Beamish (22) or Beamish and Van Loon. (23)

The lead bead can also be analyzed for precious metals by ETAS, (24) solvent extraction–FAAS (25) or by polarography, (26) although these techniques are rarely used.

Rh, Ru, Ir and Os are not determined as frequently as Au, Pt and Pd, and their concentrations are usually much lower in ores. If their determination is required, however, the sample is fused with a mixture of Ni powder or Ni oxide powder and sulfur. This produces a nickel sulfide matte, similar to that produced in a smelter. (27) The precious metals are collected in the matte. Pt and Pd are also collected and can be added to the determination suite. Au is not collected completely, (27–30) recoveries being 75–90%. Results from this collection procedure should be used as a rough guide, but if the Au content is low, the incomplete recovery may not be economically significant. The NiS button is pulverized, dissolved in hydrochloric acid and the insoluble precious-metal sulfides are filtered off. They may be dissolved in a mixture of H2O2 and HCl, contacted with an ion-exchange resin to remove traces of Ni. Rh, Ru and Ir can then be determined by FAAS or ICP-OES. The removal of traces of Ni is critical if ICP-OES is the technique used, owing to spectral interferences. If FAAS is used, traces of Ni do not interfere. Os is lost during the dissolution. A separate fusion with a different dissolution is required for the determination of Os. Alternatively, the NiS button is divided after the pulverization step, with part being used for the determination of Rh, Ru and Ir and the other part for Os. Os is very insensitive by FAAS and ICP-OES. It can be determined wet chemically by fusing the precious metal residue with sodium peroxide, dissolving the melt in nitric acid, extracting Os into toluene, then back-extracting into a solution of thiourea to form a colored
and would take much longer. For an inquart to be used, it must be certified and has not found wide acceptance by laboratories.

Other attacks were incomplete, based on chemical assay lead collection method if no inquart is utilized. The beads are weighed on a microbalance, then dissolved in aqua regia and Au is determined by FAAS or ICPOES. Ag and Au can be determined by the classical fire assay lead collection method if no inquart is utilized. The bead is weighed on a microbalance, then dissolved in aqua regia and Au is determined by FAAS or ICPOES. Ag is determined by difference. If the bead is spongy or black, there may be other precious metals present, and the dissolved solution should be checked for Pt and Pd.

Faye and Moloughney(36) proposed tin as a collector for the determination of the platinum-group metals, gold and silver. This method requires considerable skill to use, and has not found wide acceptance by laboratories determining precious metals.

Zheng and Cui(37) determined Pd by absorbing Pd on polyurethane foam, wet ashing the foam and determining Pd by ETAS.

Kolosova et al. reported the determination of Os by ETAS.(38)

Kinetic methods for the determination of Pd,(39) Rh(40) and Os(41–43) have been reported.

The determination of platinum group elements and Au by accelerator mass spectrometry has been reported.(44)

**Warning:** Some laboratories have attempted to determine precious metals in ores by dissolution with aqua regia followed by analysis of the solution by ICPOES. False positives are inevitably reported owing to spectral interferences from iron. Occasionally, there are reports that the precious metals are present in a form (unknown) that prevents their determination by conventional assay techniques. In these cases, it is best to determine the precious metals by the nickel sulfide collection procedure, since this mimics the actual production step of converting the ore concentrate into a matte. If the precious metals cannot be recovered by the production process, then the ore alleged to contain precious metals is worthless to the smelter.

### 3.2.1.5 Determination of Silver by Wet Chemical Methods

This procedure is best suited for low concentrations of Ag (0.5–800 g t⁻¹, although an upper limit of 200 g t⁻¹ is commonly observed). The sample (usually 2 g) is first oxidized with a small amount of bromine, then attacked with aqua regia and 1–2 mL of hydrofluoric acid (to help decompose silicates). The digested sample is transferred to a volumetric flask, acidified to 25% v/v hydrochloric acid and the Ag is determined using matrix-matched standards. The bromine oxidation step is needed to prevent low recoveries of Ag.(45)

### 3.2.2 Elements of Environmental Concern (Sulfur, Mercury, Selenium, Tellurium, etc.)

Sulfur emissions from smelters have been a concern for many years. Increasingly strict regulations have required smelter operators to invest heavily in metallurgical research and plant capital. The accurate determination of S is therefore critical in the evaluation of an ore. The most common method is by combustion of the sample at high temperature in a ceramic crucible or boat in a stream of oxygen. The S is converted to SO₂, which is determined by passing the combustion gases through a dedicated infrared (IR) cell. The instrument is calibrated using reference materials with known total sulfur content. The detection cell must be capable of reading high sulfur levels (in the range 5–25% by weight). If the instrument cell cannot determine such high levels without saturating the detector, then smaller than normal sample weights must be used, with a consequent decrease in accuracy. The instrument manual should be consulted if there is any doubt. Older instruments would pass the combustion gases, the sulfur now present as sulfur dioxide, into acidified starch–iodide solution and titrate with potassium iodate solution. This old method may still be encountered, and is well suited for massive sulfide ores. Another old technique which may be encountered is to absorb the sulfur dioxide in a 5% solution of sodium peroxide and titrate the acid formed with sodium hydroxide.

Inco(8,10) has developed a routine procedure whereby the sample is fused with sodium peroxide. The sulfides are converted to sulfates, which are not volatile upon acidification with hydrochloric acid. The sample solution is then analyzed by ICPOES.

If total sulfur is to be determined by the classical gravimetric procedure (precipitation as BaSO₄), then the sulfides must be oxidized to sulfates. This can be accomplished by allowing the sample to stand in contact with a few milliliters of bromine plus a little water for at least 15 min at room temperature. Nitric acid is then added.
and the sample is heated gently on a hot-plate to complete the oxidation and to remove Br2. When dissolution ceases, the insoluble matter is removed by filtration and the sulfur (now present as sulfate) is determined in the classical manner. This procedure is not used for routine analyses, but still finds a place in the analysis of samples to be used as reference materials. Details of this method can be found in classical analytical texts such as Kolthoff and Sandell.\(^{46}\)

Sulfur has also been determined by XRF.\(^{47}\)

Mercury is found in trace amounts in many ores. Even at very low levels \((<0.1 \text{ g t}^{-1})\), there are concerns owing to the high tonnages of ore processed by smelters. Owing to its volatility, Hg is assumed to be lost to the environment in stack emissions. Most laboratories use variations of the cold vapor method developed originally by Hatch and Ott.\(^{48}\) Recovery studies are critical, since some elements often found in nickel sulfide ores (such as Se and Te) may inhibit the reduction of Hg to the elemental form. During the dissolution, the sample should be kept oxidized (KMnO\(_4\)), and the temperature kept below 90 °C, or reflux conditions should be used. Tartaric acid is used to complex base metals during the reduction of Hg. In the presence of vegetation, if charring occurs, Hg will be reduced to its elemental form and lost. Blanks are critical since even the reagents may contain Hg at concentrations similar to the samples.

Se and Te are often encountered in sulfide ores. Some may also be lost during smelting via stack gases, although much is retained in the matte. The presence of Se and Te in the matte is a concern to nickel refineries, which must separate them from the Ni. The hydride evolution AAS method does not work well for the determination of Se and Te owing to the presence of Ni and Cu. If the Ni concentration is fairly low \((0.5–1\%)\), then complexing agents such as hydroxylamine or cysteine may be added before the reduction step. It is better to oxidize the sulfide ore sample with bromine, then dissolve Se and Te with nitric acid and determine them by ETAS.

Te has also been determined by polarography.\(^{49}\)

Depending on the ore body, other trace and minor elements may also be required. As, Cd and Sn are frequently required. In ores they are often present only in traces, and can be determined by ETAS after dissolution by the bromine–nitric acid attack described above.

### 3.2.3 Other Elements (Iron, Silicon, Aluminum, Magnesium, Calcium)

These elements are critical to the smelter, since they will all eventually report to slags. They may be determined wet chemically by FAAS or ICPOES by dissolutions described in section 3.2.1.1. They may also be determined by XRF on briquettes if the ore body is reasonably homogeneous. If more than one ore body is being processed, then each body must have its own XRF calibration curve.

Classical methods (redox titration for Fe, complexometric titrations with EDTA for Al, Ca and Mg,

gravimetry for Si) can also be used, although these methods are relatively slow and labor-intensive. Reports occasionally appear in the literature (Al\(^{50}\), Ca and Mg\(^{51}\)).

3.2.4 Recommended Methods

Table 1 sets out recommended methods of analysis for sulfide ores.

3.3 Analysis of Nickel Laterite Ores

Bibent and Bufferne\(^{52}\) reviewed methods of analysis for New Caledonian laterites. Owing to the clay-like nature of laterites, the determination of moisture is critical to accurate analyses. Lopez et al.\(^{53}\) discuss the determination of moisture in Moa laterites.

For practical, routine purposes, the pulverized sample should be dried and stored in an oven at 105\(^\circ\)C. If, however, a very accurate analysis is required, e.g. for settlement or for validation of a reference material, then the best way to obtain an accurate analysis is to weigh two portions of the pulverized sample, one for the elemental analysis and the other portion for moisture, and correct to a dry weight basis. Because this is critical, the determination of the moisture content is described in some detail below (section 3.3.1).

Since laterites are extremely hygroscopic, storage in a desiccator is not recommended. The dried ore will absorb moisture from the desiccant, even if the desiccant is fresh, and will absorb moisture from the air each time the desiccator is opened.

3.3.1 Pay Metals (Nickel, Copper, Cobalt)

Ni is the element of greatest concern. Usually only small amounts of copper and cobalt are present. If significant amounts of Co are found, it is wise to check to make sure that the crushing and grinding equipment is not made of cobalt alloy (e.g. Stellite\(^{\text{TM}}\)). This has caused problems in some laboratories, where falsely high Co results have been reported. Caution should also be exercised if tungsten carbide pots are used. These pots may contain up to 6% Co (used as a “cement” to tie the tungsten carbide particles together).

For accurate results, a correction for moisture must be made. It cannot be stressed enough that the conventional procedure of drying at 105 \(^\circ\)C and storing the sample in a desiccator will yield low, inaccurate results owing to moisture pick-up by the sample from the desiccant. In fact, a dried or partially dried sample can be seen to gain weight on a balance if the laboratory atmosphere is at all humid.

The best way to obtain the moisture correction factor is as follows:

1. Weigh the analytical sample into a beaker (for wet chemical analysis) or crucible (for ICPOES or XRF analysis).
2. Immediately thereafter, weigh a 5-g sample for moisture content determination, into a tared, dry glass weighing bottle plus tared lid.
3. Place the weighing bottle in an oven at 105\(^\circ\)C with the lid ajar to allow moisture to escape. Heat for at least 2 h.
4. Remove the weighing bottle from the oven and place in a desiccator containing fresh desiccant. Tap the bottle to cause the lid to seat into the top, closing the bottle. This must be done as rapidly as possible on removing from the oven.
5. Close the desiccator and allow the bottle to cool to room temperature. The cooling will create a slight vacuum inside the closed bottle, pulling the lid down snugly and preventing moisture from the inside of the desiccator from reaching the sample.
6. When cool, weigh the bottle and contents without removing the lid. The moisture content of the sample can then be calculated, and used to correct the analytical results to a dry basis.

3.3.1.1 Determination of Nickel by Wet Chemical Methods

Dissolution of the Sample. The dissolution described in the section on dissolution with mineral acids above may be used. There will be more dissolved solids than with sulfide ores since there is little S present to be volatilized as H\(_2\)S.

Nickel by Classical Precipitation with Dimethylglyoxime. The procedures described in the section on determination of nickel by classical wet chemistry may be applied. For accurate results the procedure for moisture correction detailed in section 3.3.1 must be followed.

Nickel by Flame Atomic Absorption Spectroscopy or Inductively Coupled Plasma Optical Emission Spectroscopy. The procedures described in the section on determination by FAAS or ICPOES may be applied. For accurate results, the moisture correction must be made, and the final (uncorrected) result should be determined by using close-bracketing calibration standard solutions. For ICPOES these standard solutions must be matched in acid strength to the samples, and the acid strength of the samples must be tightly controlled.
Gedeon et al.\textsuperscript{(54)} compared digestion techniques for FAAS analysis and concluded that a mixture of HF and perchloric acid was best to achieve complete dissolution of the sample. They also compared the results to those obtained by XRF.

\textit{Copper and Cobalt by Flame Atomic Absorption Spectroscopy or Inductively Coupled Plasma Optical Emission Spectroscopy.} The solution used for the determination of Ni (see the previous section) may also be used for Cu and Co.

3.3.1.2 \textbf{Analysis of Nickel Laterite Ores by X-ray Fluorescence Spectroscopy} XRF has been a popular technique for the analysis of laterites.\textsuperscript{(56--61)} In a commercial laboratory,\textsuperscript{(59)} the samples are fused with lithium tetraborate in a platinum crucible at a ratio of 0.5 g of sample to 7 g of lithium tetraborate. A small amount (0.5 g) of LiBr is added to the mix as a releasing agent during the pouring of the melt. The melt is poured into a platinum dish and cools to a glassy disk. The use of platinum ware is possible since laterites contain only small amounts of sulfur. High (>3\%) Ni ores can also cause problems owing to the formation of an alloy with the Pt crucible. This will result in carryover to subsequent samples. For high-Ni samples, a smaller sample weight should be used. The disk is then analyzed for Ni, Co, Fe, Cr, Ca, Mg, Na, K, Mn, Ti, Al and Si. The disk is very stable and can be stored indefinitely. Loss on ignition (LOI) is also performed on a dried sample at 1000°C, and gives a measure of the water of crystallization, carbonates, sulfides and some graphite. If trace elements are desired, e.g. Cu, P, Zn, a briquette is made by pressing into a pellet with a suitable binder. The briquette is also fairly stable, but is prone to pick up moisture. If further analysis of the briquette is contemplated, it must be stored in a desiccator and inspected before it is analyzed again (the briquette will swell markedly on picking up moisture).

The pressed pellet technique described earlier is very suitable for the routine analysis of laterites. It is best, however, to let the ore equilibrate with the moisture in the laboratory atmosphere before making the pellet. As is the case with sulfide ores, the calibration curve is specific to the ore zone being analyzed.

3.3.2 \textbf{Neutron Activation}

This technique is popular for exploration and bulk sample analysis.\textsuperscript{(61--64)}

3.3.3 \textbf{Elements of Environmental Concern (Sulfur, Mercury, Selenium)}

Sulfur is usually present in low concentrations (<1\%) and can be determined by combustion instruments. Owing to the large amount of water of crystallization found in laterites, the moisture trap on the instrument must be checked frequently. A good indication of problems is if the SRM used to monitor performance (every tenth sample) gives a poor result.

Hg can be determined by the cold vapor technique, with relatively few interferences likely to be encountered. Dissolution can be effected with aqua regia and KMnO\textsubscript{4} as an oxidant. If vegetation is present in the sample, care must be taken to avoid charring of the organic matter, since this will instantly reduce Hg to the elemental state and it will be lost.

Se is also usually present in trace amounts (<5 g t\textsuperscript{−1}). Se can be determined at these levels by hydride evolution AAS if precautions are taken to overcome interference by Ni (see above) or by ETAS. If the latter technique is used, beware that the large amounts of Fe present in the ore will interfere with the measurement if the deuterium background correction is used. There should be no such problem if the instrument uses the Zeeman or Smith–Hieftje corrections. Alternatively, Se may be collected using As and determined by conventional ETAS.

Other trace elements such as As, Cd and Te are not commonly determined in laterite ores.

3.3.4 \textbf{Other Elements (Carbon, Iron, Silicon, Aluminum, Magnesium, Calcium)}

3.3.4.1 \textbf{Carbon by the Combustion Technique} C is determined using combustion techniques, with the same caveat regarding the moisture trap as described in section 3.3.3.

3.3.4.2 \textbf{Iron, Silicon, Aluminum, Magnesium and Calcium by Wet Chemistry} For routine analyses, the sample may be dried and stored at 105°C. If very accurate results are required (e.g. for the certification of reference materials), then the moisture correction procedure in section 3.3.1 should be followed.

\textit{Routine Analyses.} A 0.25-g sample may be fused in a Zr crucible with Na\textsubscript{2}O\textsubscript{2}. The cooled melt is dissolved in water and then acidified to 20\% \textit{v/v} HCl in a 250-mL volumetric flask. The solution should be clear. Any insoluble matter (usually silica) should be filtered off and re-fused to obtain a completely dissolved sample. The sample solution is analyzed by either FAAS or ICPOES against matrix-matched standards.

Alternatively, dissolve the sample with HCl, filter off the insoluble matter, fuse the latter with Na\textsubscript{2}O\textsubscript{2} in a Zr crucible, dissolving the cooled melt in water and acidifying with HCl as described above. The solutions are made up to volume separately and are analyzed
by FAAS or ICPOES using matrix-matched calibration solutions.

**Miscellaneous.** Ahmad and Morris\(^{(65)}\) determined Cl by neutron activation.

**Reference Material Quality Analyses.** For Fe, Al, Ca and Mg, the sample may be dissolved in HCl, the insolubles filtered off and fused as described in the alternative procedure in the routine analyses section above. Fe may be determined on an aliquot of the sample solution by redox titration (e.g. with potassium dichromate). Ca and Mg may be determined by EDTA titrations after separating the Fe and Al by precipitation with ammonia solution (the classical R\(_2\)O\(_3\) separation). Al may also be determined by EDTA titration after separating Fe by ion exchange. Residual Fe, Ca, Mg and Ca present in the acid insoluble matter may be determined by FAAS or ICPOES, and added to the values determined by titration.

Silica is best determined on a separate sample. The sample is attacked first with HCl, then taken to strong fumes with perchloric acid (HClO\(_4\)) to dehydrate the silica. The residue after fuming is taken up in dilute HCl, filtered, washed well to remove HClO\(_4\), ignited in a platinum crucible, and silica determined by difference upon volatilization with hydrofluoric acid (HF).

**3.4 Quality Control for the Analysis of Nickel Ores**

While exact quality-control procedures vary from laboratory to laboratory, at the least, the following controls should be run:

1. Certified reference materials or in-house secondary standards which have been validated against certified standards. For nickel sulfide ores, the Canadian Certified Reference Materials Project (CCRMP), organized by CANMET, a federal government agency, is a source of well-proven materials. For nickel laterites, the International Geological Survey (IGS) is a good source, particularly materials IGS 22 and IGS 23. See also Potts et al.\(^{(66)}\) for a more complete listing of ore standards.

2. Randomly selected replicate samples at frequent intervals.

3. Procedure blanks.

**Caution should be used with reference materials.** The certified Ni content of each material is a consensus value based on the results from many laboratories using different analytical techniques. The analysts who generated the data possess varying degrees of experience in the analysis of nickel ores. Occasionally, further analysis by experienced laboratories will give a more reliable result. If there is any doubt as to the accuracy of a certified reference material, the certifying body should be contacted. In the case of the IGS laterites, not all of the participating laboratories may have been aware of the hygroscopic nature of the laterites. Consequently,
the certified values of the IGS reference laterites may be slightly low.

4 ANALYSIS OF NICKEL METAL

Refined nickel metal is produced in various shapes and sizes: powder, briquettes and rondelles, granular nickel and nickel shot, carbonyl pellets and cathode nickel. High-purity refined nickel is used by stainless-steel and high-Ni alloy producers and in the plating industry. Less pure nickel may be used by steel producers to make low-alloy steel. The minor impurities will be diluted in these steels to the point where their effect on the steel will be negligible for the particular application.

4.1 Common Forms of Refined Nickel Metal

The most common forms of refined nickel are nickel pellets (produced by the carbonyl process) and nickel cathodes.

**Carbonyl pellets** are spherical and range in size from 0.5 to 2 cm in diameter, with most being about 1 cm. The growth is by layers, and a cross-section under a microscope resembles an onion.

**Nickel cathodes** are usually about 0.7 m wide and 1 m long. They are harvested from the plating tank when they are about 0.5 cm thick. They may be shipped in this form, but most often are sheared into squares or rectangles, the most common being 1- and 2-in squares. These squares are shipped in drums of 50, 250 or 1000 kg capacity. Another form of cathode nickel is produced primarily for the plating industry. It is most often a circular piece of metal, roughly one inch in diameter (smaller sizes are also produced), grown by electrolytic deposition onto a stainless-steel stud and then removed when the desired size is achieved. This type of product has no sharp edges (unlike the sheared cathode squares or rectangles), and can be loaded into anode baskets in plating shops without tearing the baskets. This product may also be made in a plating bath containing sulfur compounds which will react during the electrolytic deposition to form a sulfur-depolarized nickel product which has dissolution properties desired by some nickel platers.

**Nickel powders** of different degrees of purity are also produced either by the carbonyl process or by extraction/reduction processes. These may be delivered as the powder or may be compacted into pillow-shaped briquettes or rondelles weighing 50–100 g for easier handling in foundries.

**Granular nickel** (often relatively impure) is also produced. It is about 1–2 mm in diameter, roughly spherical, but larger, irregular blobs may be present.

Each form presents its own problems in sampling, but once a representative sample is obtained, the analysis remains much the same regardless of the original form. The sampling of the various common forms and the preparation of the analytical sample is discussed below. For a detailed description of sampling, see ISO 7156.

4.1.1 Sampling and Sample Preparation of Carbonyl Pellets

These are spherical, ranging in size from 5 to 20 mm in diameter. They are usually shipped in drums of 50, 250 or 1000 kg capacity. Owing to size variations, there can be segregation within the drum. This is usually not too important owing to the high purity of this material. A number of drums are randomly selected. Pellets are scooped out from each drum, blended and split down until a 200-g representative sample is obtained. Small pellets may be analyzed directly, but larger ones should be drilled or machined to obtain chips. The chips are blended to form the analytical sample.

If there is concern that the variation in purity is great within a drum, then the entire contents of the drums selected must be dumped out and properly sampled by quartering or alternate shoveling techniques. The final sample should then be prepared by drilling or machining chips and blending. A detailed sampling procedure is given in ISO 7156.

Carbonyl nickel is usually very pure, with the exception of carbon content, and, from some older refineries, iron can be found in the 50–150 g t⁻¹ range. Care must be taken during sample preparation not to contaminate the sample. Small amounts of cutting tools can abrade off into the sample during preparation. No lubricants should be used. If, by mistake, a cutting lubricant has been used, it must be removed with an appropriate solvent, such as acetone, prior to analysis.

4.1.2 Sampling and Sample Preparation of Nickel Cathodes

**Whole cathodes** weigh about 50 kg. ISO 7156 provides a detailed sampling scheme. Briefly, a random number of whole cathodes are selected, and each is sampled in five places along the diagonal from the top corner to the center of the cathode. The samples may be obtained by drilling completely through the cathode, milling a hole through the cathode or punching a hole through the cathode and milling the punch piece. The recommended hole diameter is between 15 and 25 mm. The drills or millings are then combined and blended. If more than one laboratory is to analyze the sample, the chips should be divided by riffling, alternate shoveling or coning and quartering.
Sheared cathode pieces and round pieces produced for the plating industry are shipped in drums of 50, 250 or 1000 kg capacity. A number of drums are randomly selected and one or more pieces are taken from each drum, machined or drilled, and the chips combined and blended to form the analytical sample.

Cathode nickel may be very pure, comparable to carbonyl nickel. Less-pure cathode nickel is also produced. Regardless of the source of the nickel, care must be taken during sample preparation not to contaminate the sample. Small amounts of cutting tools can abrade off into the sample during preparation. No lubricants should be used. If, by mistake, a cutting lubricant has been used, it must be removed with an appropriate solvent, such as acetone, prior to analysis.

4.1.3 Sampling and Sample Preparation of Briquettes and Rondelles

An appropriate number of pieces are taken from randomly selected drums (see ISO 7156). The pieces, weighing typically 50–100 g depending on the producer, are then machined or otherwise broken into chips and the chips blended and riffled to obtain a final sample of about 500 g. Care must be taken during sample preparation not to contaminate the sample. Small amounts of cutting tools can abrade off into the sample during preparation. No lubricants should be used. If, by mistake, a cutting lubricant has been used, it must be removed with an appropriate solvent, such as acetone, prior to analysis.

4.1.4 Sampling and Sample Preparation of Granular Nickel (Including Fine Shot, Nickel Metal Powders)

The material is usually shipped in drums, of 50, 250 or 1000 kg capacity. Depending on the number of drums in question, a random number are selected (see for example ISO 7156), the entire contents of the drums are emptied, blended as well as possible and the mass is reduced to a reasonable size by alternate shoveling or riffling. About 200 g should be sufficient for powders and 500 g for granular nickel and fine shot. This lengthy procedure is necessary since the contents of the drums will segregate in transit. A grab sample, obtained by scooping from a drum or drums, may suffice for spot checking. No particle size reduction is required.

4.2 Determination of Trace Impurities

Once in the laboratory, the analyst should reblend the entire sample to minimize segregation effects. A knowledge of the history of the sample is advantageous. The more homogeneous and purer the material, the smaller the actual analytical sample can be. The minimum sample size should be 1 g. For impure and/or heterogeneous material, a larger weight should be taken (10–15 g).

Trace elements in nickel metal are often <0.001% in concentration. For this reason, great care must be taken during the sample preparation and dissolution so as not to introduce contaminants. As an example, touching the sample with bare skin will contaminate it with sodium. If surface contamination is suspected, either through touching or from tools used to generate chips, a quick rinse with warm, dilute HCl (also known as pickling the sample) followed by a thorough rinsing with water will remove virtually all such contamination.

4.2.1 Dissolution of the Sample

The sample is dissolved with 1:1 nitric acid for the determination of trace-metal impurities. Care must be taken at this stage to add the acid in small increments, allowing the reaction to subside between additions. Failure to follow this procedure can lead to an extremely vigorous reaction, foaming over the top of the beaker, and possibly spraying acid on to the analyst. This is particularly true for powders. Very high-purity nickel chips may be much slower dissolving and gentle heating may be required to initiate and/or maintain the reaction. Occasionally a sample will dissolve slowly at first, then accelerate very rapidly with foaming. It is wise to have a squirt bottle of water at hand to quench vigorous reactions.

For impure materials, there will be some insoluble matter left after the metal has dissolved. This should be filtered off and retained for further analysis. For carbonyl powders, there may be considerable carbon which should also be removed by filtration. The dissolved portion should be transferred to a clean volumetric flask, so that the final nickel concentration is 2–10% w/v (this varies from laboratory to laboratory, depending on how the analysis is then conducted).

4.2.2 Determination of Trace Impurities

Once into solution, the analysis is commonly carried out using several different techniques, depending on the element and its concentration range. Before the introduction of ETAS into common use in the mid-1970s, trace elements were determined by FAAS or by solvent extraction/colorimetric methods [e.g. Co in nickel by solvent extraction/colorimetry, Sn by ion exchange/colorimetry]. These methods were proving unsatisfactory owing to their relative insensitivity (FAAS) and length of time required (colorimetry). Refiners were improving their processes to produce better quality nickel, and a number of attempts were made to improve analytical detection limits. Preconcentration methods were
proposed including extraction of traces with trioctylphosphine oxide (TOPO) into methyl isobutyl ketone (MIBK) and analyzing by FAAS,\(^\text{70–73}\) coprecipitation of Pb and Bi with manganese dioxide\(^\text{74}\) and extracting several trace elements with sodium diethyldithiocarbamate followed by FAAS,\(^\text{75}\) As these procedures were gaining acceptance, reliable ETAS instruments and lamps (electrodeless discharge lamps for Bi, Se, Te, As and Sb) became available, and the preconcentration work was abandoned. Direct injection of the dissolved sample into an electrothermal atomic absorption spectrometer is very simple, eliminates sources of contamination, is relatively fast,\(^\text{76,77}\) and can be automated. Calibration is usually done by the method of standard additions.

Today a combination of FAAS, ETAS, ICPOES, ultraviolet/visible (UV/VIS) spectrophotometry, combustion and fusion instruments is required for the complete analysis of nickel metal, and the concentration level of the impurity can dictate the technique chosen. For example, Shvarts et al.\(^\text{78}\) used FAAS to determine Co, Cu, Fe, Pb and Zn. Kiyokawa et al. determined Si by distillation/colorimetry,\(^\text{79}\) but this procedure is not suited for routine use.

At the time of writing, at least one laboratory was still using an optical emission spectrograph (the method detailed in Lewis et al.\(^\text{1}\)) for several elements, as well as the other techniques.

Analysis by neutron activation\(^\text{80,81}\) is not easy owing to interferences from \(^{58}\)Co, necessitating the removal of the Co by solvent extraction and counting the aqueous phase.

Taylor et al.\(^\text{82}\) determined low levels of Co by ion-exchange/ICPOES and ETAS. ICPOMS has also been tried.\(^\text{83}\) The difficulty with this technique is the low tolerance for dissolved solids.

Interestingly, the multielement analysis capabilities of ICPOES have led to renewed interest in preconcentration techniques with lanthanum hydroxide\(^\text{84}\) or yttrium hydroxide to isolate many of the trace elements. The metal sample is dissolved in nitric acid and a small amount of La or Y is added. Excess ammonia solution is added to precipitate the La or Y as a floc and form a soluble nickel ammine complex. The floc adsorbs many trace impurities. The floc is filtered off, dissolved in a small amount of nitric acid and diluted to a relatively small volume. Frequently the equivalent of 10 g of initial sample may be concentrated in 10 mL. The solution is then analyzed by ICPOES. Inco prefers the use of yttrium since it has a simpler spectrum in ICPOES and first applied it to the analysis of high-purity copper.\(^\text{85}\) Inco subsequently applied the Y collection/ICPOES procedure to the analysis of nickel. The yttrium hydroxide collection/ICPOES method has been in routine use at Inco’s Copper Cliff refinery for a number of years and is under review by ISO TC155/SC3/WG5 as a proposed routine method of analysis at the time of writing this article. Inco is currently considering ICPMS\(^\text{86}\) with Y collection as a substitute for ICPOES since it permits the analyst to use smaller samples to achieve comparable detection limits. Smaller samples require less handling time, particularly at the sample dissolution and precipitation steps. The collection procedure should be used with caution since not all of the traces are collected quantitatively. Recovery studies must be made and correction factors introduced in order to obtain accurate results. This is especially true for Pb, where the collection efficiency tends to be erratic. Calibration curves are produced by the method of standard additions applied to solutions of high-purity nickel, and then carried through the collection steps.

ISO methods are available for the FAAS determination of Ag, Bi, Cd, Co, Cu, Fe, Mn, Pb and Zn (ISO 6351) and for the ETAS determination of Ag, As, Bi, Cd, Pb, Sb, Se, Sn, Te and Ti (ISO 7523).

Table 3 sets out the elements determined and recommended methods of analysis for high-purity nickel. For less pure samples, it may be necessary to dilute to sample solution, or to choose a less sensitive technique, e.g. FAAS instead of ETAS.

Carbon and sulfur (and oxygen, nitrogen and hydrogen if desired) are determined on separate analytical samples by combustion (or fusion) instruments. The detectors for most carbon and sulfur determinators are IR cells (see e.g. ISO 7524 for the determination of carbon and ISO 7526 and 7527 for the determination of S). For the gases, gas chromatography (GC) with dedicated gas chromatographs is used to measure the evolved gases after heating (fusing in a graphite crucible) at high temperatures. For pellets and cathode nickel, the gases are better determined on small pieces, about 1 g, cut from larger pieces or pellets. Several determinations should be made using samples from different pieces and the results averaged. Powders are not normally analyzed for gases owing to the large surface areas.

A sensitive method for the determination of sulfur is by dissolution of a sample in a mixture of nitric and hydrochloric acid, removal of nitrates, reduction of the sulfate to H\(_2\)S and distillation into a solution containing N,N-dimethyl-p-phenylenediamine to form methylene blue. Contamination from sulfide samples elsewhere in the laboratory is a major concern. Consequently, this method is not in widespread use. For details of the method, see ISO 7525.

Another possibility is the determination of S by ICPMS, although the literature survey did not uncover any reference for this.

Occasionally other elements may be requested, as listed in Table 4.

* Determined on solid samples.

Refactory elements are rarely requested. ICPMS is the simplest technique to use. Otherwise, the sample must undergo a preconcentration step whereby a large sample weight is subjected to treatment with CO to remove nickel as the carbonyl, leaving the refractories behind in the residue. This is extremely hazardous, both from a toxicity point of view and from the risk of explosions.

4.3 Quality Control

Procedure blanks and reference materials should be analyzed with the batch of samples. Contamination is the greatest concern at the very low levels of trace impurities encountered in high-purity nickel. Reference materials with impurities at current production levels may be obtained commercially from Brammer Standards and Analytical Reference Materials Inc. Well-analyzed secondary standards (real samples of very high-purity nickel) may also be used. The National Institute of Standards and Technology (NIST) has three nickel oxide reference materials, but owing to their high impurity levels they are not recommended.

5 ANALYSIS OF NICKEL OXIDES

Some refineries produce crude nickel oxide sinters as their final product. Others produce high-purity nickel oxide which is made for sale to the chemical market. The two must not be confused.

Crude nickel oxide sinters have varying amounts of nickel (70–90%) and considerable gangue, mainly silica, alumina, calcium and magnesium. The concentrations of other impurities, particularly cobalt and copper, are much higher than in refined nickel metal. Such material is sold in small irregular lumps, and is used to make low-alloy steels. The gangue will slag off, and the relatively high impurities will be well diluted.

High-purity nickel oxide is sold as a powder mainly into the chemical market and consequently has impurities at very low levels, comparable to those found in high-purity nickel metal.

5.1 Sampling and Sample Preparation

5.1.1 Nickel Oxide Sinters

The lumps may be sampled in a manner similar to that described in section 4.1.3. The lumps are generally friable and the analytical sample can be prepared by crushing and blending.

5.1.2 High-purity Nickel Oxide

This material can be sampled in the same way as nickel metal powder described in section 4.1.4.
5.2 Sample Dissolution and Analysis

5.2.1 Crude Sinters

Crude sinters are produced by high-temperature roasting of nickel sulfide and are very refractory. They may be attacked with warm, dilute (1:1) nitric acid. Considerable insoluble material may be left, which should be filtered off, fused with sodium peroxide and analyzed separately by FAAS or ICPOES for the gangue elements. The other trace elements can be analyzed similarly to nickel metal in the nitric acid-soluble portion, although there may be dilutions required, or alternative, less-sensitive techniques substituted (e.g. FAAS instead of ETAS). Another approach is to dissolve the sinter by fuming with perchloric acid, with filtration and fusion of the insoluble residue (mainly silica). The combined solution can be analyzed for major impurities and gangue elements by FAAS or ICPOES.

5.2.2 High-purity Nickel Oxide Powder

Dissolution is accomplished with warm, dilute (1:1) nitric acid. There should be very little, if any, insoluble residue left. The solution can be analyzed in the same manner as nickel metal above.

5.2.3 Determination of Nickel in Nickel Oxides

The material is sold on the basis of nickel content. Ni can be determined by the classical precipitation with DMG, with a gravimetric or EDTA titration finish. Ni can also be determined gravimetrically by the electrolytic deposition method. This method is in use in production laboratories, and has been accepted by ISO as an umpire method (ISO 12169).

5.2.4 Determination of Oxygen in Nickel Oxides

Nickel oxides, regardless of purity, have oxygen as a major element. Commercial oxygen determinators work best at low (parts per million) levels, not at 20%. A good way to determine oxygen is by gravimetry. A sample is reduced under hydrogen at 400°C in a tube furnace, and the weight loss is assumed to be oxygen. Residual oxygen associated with gangue matter can then be determined by a commercial oxygen determinator, and the results combined give the total oxygen present in the sample.

5.3 Quality Control

For high-purity nickel oxide, the same quality control criteria cited under the analysis of nickel metal apply. For nickel oxide sinters, the NIST nickel oxide reference materials may have some use.

6 FERRONICKEL

Ferronickel is produced by smelting laterite concentrate and ranges from 15 to 50% nickel, the balance being iron, with minor and trace impurities. It is used in the stainless-steel industry, where the producers obtain high-quality iron units, often at no cost, along with the nickel. Ferronickel is produced as ingots, lumps or granules.

6.1 Sampling and Sample Preparation

6.1.1 Granules

ISO 8049 sets out a rigorous procedure for the sampling of ferronickel granules. Once the containers (trucks, drums, etc.) have been sampled, the granules are blended and divided by riffling or alternate shoveling until the mass is 1–5 kg, depending on the shipment size. The granules are melted in 1-kg batches, preferably in an induction furnace under argon, and sample bars are cast. These bars can be sliced to obtain disks for XRF analysis, or be drilled or milled to obtain chips for wet chemical analysis and for the determination of carbon and sulfur. Caution: Some ferronickels are very hard, and appropriate tools must be selected. If cutting lubricants must be used, then the sample must be washed with a suitable solvent such as acetone to remove the lubricant, and then dried to remove the solvent.

6.1.2 Ferronickel Ingots or Pieces

ISO 8050 gives a good description of the sampling protocol. Briefly, if the sampling is done during casting, a spoon sample is poured into a suitable mold to form a bar. The bar may be sliced and/or milled as described in section 6.1.1. When sampling ingots or pieces, there is a different protocol depending on whether or not the shipment is from the same heat or from more than one heat. If the shipment is from one heat, then only five ingots or pieces are randomly selected. If there is more than one heat present or suspected to be present in the shipment, then the number of ingots or pieces selected must be increased dramatically. The number depends on the lot tonnage.

Once the ingot or pieces have been selected, the surface must be cleaned before drilling or milling. Since ferronickels can be very hard, annealing the ingots or pieces may make drilling easier. If lubricants are used during the drilling or milling, the chips must be washed with a suitable solvent such as acetone, then dried and blended. For lots comprised of only one heat, there is no need to do rigorous blending. In the case of more than one heat, the sample must be homogenized. If the nickel content is <35%, the sample may be brittle enough
to crush. This can be done in a laboratory vibratory cruiser, preferably made of tungsten carbide. The fine particles are thoroughly blended. Ferronickels with nickel contents >35% are too ductile to be crushed and the drillings or millings must be blended as well as possible. In extreme cases, it may be necessary to melt the chips under argon to cast a homogeneous bar as described in section 6.1.1.

6.2 Analysis of Ferronickel

6.2.1 Determination of Nickel Content

Ferronickel is sold on the basis of nickel content. Consequently, the determination of nickel is the most critical analysis.

6.2.1.1 Routine Determination of Nickel For routine work, Ni is best determined by XRF using slices cut from sample bars. The calibration curve may be generated by using well-analyzed secondary standards. NIST SRM 1158, containing about 40% Ni (the actual Ni percentage varies depending on the version of the SRM), is an excellent standard.

The sample slices are often rough and must be polished to remove burrs and surface blemishes. This can be done using metallographic polishing wheels or belts and various grits of polishing paper. If other elements are to be determined, such as Si or Al, then diamond polishing paper should be used in order not to contaminate the surface of the disk.

Caution: The surface of the calibration standards and the surface of the samples must be almost identical. If the standards are polished to a matte finish, then that is what must be done to the samples. If a mirror finish is used, then all must be polished in the same way.

Kholopina et al. described the use of XRF in a Yugoslavian ferronickel plant. Van Peteghem used a fundamental parameters calibration to determine the nickel content of ferronickel samples. Aleksandruk et al. determined Ni and several other elements by XRF. Lakefield Research Limited has determined nickel in ferronickel disks routinely for several years, in excellent agreement with results obtained by the umpire method described in section 6.2.1.2.

If XRF is not an option, then chips should be dissolved in warm, dilute (1:1) nitric acid and the solution analyzed by FAAS or ICPOES after appropriate dilutions. This will not produce as accurate a result as the XRF procedure described above.

6.2.1.2 Umpire Determination of Nickel ISO 6352 describes the determination of nickel in ferronickel by the DMG gravimetric procedure. This is the classical method for the determination of nickel, and variations of the method can be found in textbooks. After dissolution with nitric acid, the sample solution is taken to strong fumes of perchloric acid to dehydrate silica, which is removed by filtration. Nickel is then determined on the filtrate. Tartaric acid is used to complex iron, and sodium thiosulfate is added to complex copper if it is thought to be present. The NiDMG precipitate is filtered through tared sintered-glass crucibles and dried to constant weight at 150°C. This temperature is fairly critical. The drying temperature must be high enough to remove any absorbed excess DMG but not too high as to decompose the NiDMG precipitate.

An alternative to the gravimetric finish is to wet ash the NiDMG precipitate with nitric and perchloric acids and titrate the nickel with EDTA using murexide as the indicator. In this case, silica does not have to be removed.

Appropriate precautions should be taken when using perchloric acid.

In either case, the filtrates from the DMG precipitations must be checked for Ni by FAAS or ICPOES and a correction made to the final result.

6.2.2 Determination of Minor and Trace Elements

6.2.2.1 Determination of Carbon and Sulfur C and S are determined on chips using combustion techniques. Commercial instruments use IR detectors for the most part. Older sulfur determinators may use an iodimetric titration finish.

6.2.2.2 Determination of Minor Elements in Ferronickel Most ferronickels contain small amounts of Si, Co, Cu, Cr, Al, P and Zn. The most convenient way to determine these elements is by XRF on the same disk as is used for the routine determination of Ni. If Si and Al are determined on the disk, then the polish should be done with diamond paper to avoid surface contamination. If this option is not available, these elements can be determined by FAAS or ICPOES after dissolution with nitric acid. See ISO 7520 for the determination of Co in ferronickel by FAAS.

In some materials, the Si content is high (>1%), and not all may dissolve. Such samples are best dissolved in nitric acid, then taken to strong fumes with perchloric acid to dehydrate silica, which is removed by filtration. The silicon content of the material can then be determined gravimetrically (see ISO 8343) or by FAAS or ICPOES after fusion with sodium peroxide.

6.2.2.3 Determination of Trace Elements in Ferronickel The determination of trace elements differs from pure nickel metal in that hydroxide collection procedures are ineffective owing to the large amount of iron present in the material. The list of trace elements requested is usually shorter. In general, combustion/IR, ICPOES, FAAS and
ETAS techniques are used. Se can be a problem owing to the presence of large amounts of iron. ETAS instruments using deuterium background correction cannot determine Se below about 5 g t\(^{-1}\) (0.0005%). Those equipped with Zeeman or Smith–Hieftje background correction do not suffer from the same interference from iron. For laboratories whose instruments only have deuterium background correction, it is necessary to separate Se by collection with As.

ISO 11438 gives details of the determination of Pb, Sb, Sn, Te, Ti, Ag and In by ETAS. Arsenic is often requested since at least one ferronickel producer used laterite ore with a high As content. That ferronickel contained approximately 0.1% As. Most other ferronickels contain <0.01% As.

\(^a\) Determined on solid samples.

6.3 Summary

Table 5 sets out elements routinely determined by XRF. Aleksandruk et al.\(^{88}\) determined Cu, Co, Cr, Si, P and S by XRF. If the concentration level is too low to give an accurate result by XRF, then wet chemical methods should be used. C and S are best determined by combustion methods.

Table 6 sets out minor and trace elements commonly determined wet chemically and the techniques used.

7 ANALYSIS OF NICKEL ALLOYS

7.1 Introduction

The term “nickel alloys” covers a wide range of materials, from stainless steels containing 10–20% Ni, to heat-resistant alloys containing 30–40% Ni, to alloys where Ni is the major (>50%) constituent. There are a large number of major, minor and trace elements associated with each alloy. Since this is a very broad topic, it will be discussed in general terms, focusing on concentration ranges. Owing to the wide range of alloys, there is no single acid or acid mixture which can be used to dissolve every alloy. Where acids are recommended, it must be understood that for a particular sample, a modification of the acid or acid mixture may achieve better results. Nickel alloys are often designed to be corrosion resistant, so the dissolution may be very slow.

Owing to the difficulties of dissolution and complexities of wet chemical analysis of nickel alloys, XRF is the most widely used technique for the routine analysis of nickel alloys.

7.2 Sample Preparation

7.2.1 Chips and Drilings

Chips or drillings are commonly taken for wet chemical analysis and for the determination of C and S. Nickel alloys are often hard, and tool steels or tungsten carbide bits are used. Care must be used so as not to introduce contamination from the bit or tool into the sample.

7.2.2 Solid Pieces

For XRF analysis, the sample is often a slice cut from a test bar cast during the pouring of the alloy heat. Otherwise, a piece is cut from the part or ingot and then prepared for analysis.

For spark analysis in the field, the surface of the piece or part is simply cleaned before applying the instrument.
7.3 Determination of Major Constituents

7.3.1 By Classical Wet Chemistry

The major elements usually determined are Ni, Fe, Co, Cr and Cu (for cupronickels). Although there is no universal solvent, the best general approach is to add a small amount of water to the sample, then add diluted (1 : 1) aqua regia. The addition of water prior to the addition of the aqua regia prevents passivation of the surface of the alloy. For some alloys, particularly those containing refractory elements, the addition of small amounts of hydrofluoric acid may be required.

7.3.1.1 Nickel

Interestingly, at the time of writing, there is no consensus amongst the ISO committee on the analysis of nickel and nickel alloys (TC 155) on how best to determine Ni in nickel alloys. The best approach is to dissolve the sample in aqua regia (adding HF if refractory elements are present), and precipitating Ni with DMG as described in section 6.2.1.2. The NiDMG precipitate is often off-color, perhaps brown, and does not have the same fluffy texture of a clean precipitate. This is due to the sorption of impurities, particularly Co by the precipitate. After filtration, the precipitate is dissolved in HCl and the DMG precipitation is repeated. This usually gives a clean NiDMG precipitate which can be weighed or titrated as described above. The filtrates from the two precipitation steps are combined and are analyzed for the small amounts of Ni which do not completely precipitate. This method has been used for several years for a very wide variety of alloys by Lakefield Research Limited, covering the concentration range 10–70% Ni.

A conductometric titration has also been used for the determination of nickel.

7.3.1.2 Iron

The sample is dissolved in aqua regia, Cr is oxidized to Cr(VI), and Fe is separated from much of the matrix by precipitation with ammonia solution. The Fe is determined by redox titration with potassium dichromate (ISO 7528, covering the range 1–50% Fe).

7.3.1.3 Cobalt

The sample is dissolved in aqua regia, then fumed with sulfuric acid to remove chlorides and nitrates. Cr is oxidized to Cr(VI) and is determined by potentiometric titration with ammonium iron(II) sulfate solution. Interference from Mn is overcome by reducing the Mn(VII) with HCl. Vanadium will also titrate, giving a positive error. A correction can be made by subtracting the V content multiplied by 0.340. V can be determined by FAAS, described below. ISO 7529 covers the range 1–25% Cr. The method can be extended to higher Cr concentrations by adjusting the sample weight.

The titration can also be carried out as a conventional redox titration, with diphenylamine sulfonate as the indicator. The end-point may be off-color, depending on the alloy being analyzed. The analyst may require practice with synthetic sample solutions to discern the end-point. Some alloys, particularly those with about 35% Ni, 30% Cr and the balance Fe, can be dissolved by gentle heating in 1 : 4 H₂SO₄. This may take several hours, depending on the coarseness of the drillings or millings.

7.3.1.4 Chromium

The sample is dissolved in aqua regia, then fumed with sulfuric acid to remove chlorides and nitrates. Cr is oxidized to Cr(VI) and is determined by potentiometric titration with ammonium iron(II) sulfate solution. Interference from Mn is overcome by reducing the Mn(VII) with HCl. Vanadium will also titrate, giving a positive error. A correction can be made by subtracting the V content multiplied by 0.340. V can be determined by FAAS, described below. ISO 7529 covers the range 1–25% Cr. The method can be extended to higher Cr concentrations by adjusting the sample weight.

The titration can also be carried out as a conventional redox titration, with diphenylamine sulfonate as the indicator. The end-point may be off-color, depending on the alloy being analyzed. The analyst may require practice with synthetic sample solutions to discern the end-point. Some alloys, particularly those with about 35% Ni, 30% Cr and the balance Fe, can be dissolved by gentle heating in 1 : 4 H₂SO₄. This may take several hours, depending on the coarseness of the drillings or millings.

7.3.1.5 Copper

Copper can be determined gravimetrically, e.g. in German silver, by electrodposition on a platinum cathode. Alternatively, Cu can be titrated iodimetrically, with any Fe present being complexed with fluoride.

7.3.2 By X-ray Fluorescence Spectroscopy

XRF is by far the most widely used routine method for the analysis of nickel alloys. XRF gives fast and accurate results for the major (and minor) elements in nickel alloys. It is the preferred technique in foundries, since heats can be analyzed while still in the furnace, and adjustments in the chemistry can be made before pouring the heat. This is particularly true if a simultaneous spectrometer is used. Since the need for elaborate wet-chemical facilities is obviated, many scrap dealers prefer energy-dispersive XRF spectrometers for the analysis of metals, and can sort them quickly into different grades.

The sample should be polished to remove burrs and surface blemishes, then taken to a mirror finish, if possible (for best results). If the alloy type is known, the instrument can be calibrated with commercial or in-house secondary standards of the same matrix. If the alloy is unknown, or is a scrap sample, perhaps a mixture of several alloys, then it is best to use a fundamental parameters type of calibration. There are a variety of software packages available, and it is best to consult with the instrument manufacturer and/or a laboratory currently using such a calibration to see what software would be best for the application. In part this may depend upon whether the XRF spectrometer is wavelength- or energy-dispersive. The spectrometer manufacturer should be consulted about the application(s) and calibration standards.
For heterogeneous samples, a sufficient mass should be melted in an induction furnace, or in an arc furnace, in order to produce a homogeneous sample for analysis. If the surface area is too large relative to the mass of the sample (e.g. long, stringy drillings), it is common to start the melt with a “heel” or pieces of high-purity metal with sufficient mass to couple and melt. The drillings may then be added to the molten bath. The heel metal is an element not to be determined, and the amount added must be taken into consideration for dilution calculations. Common heel metals are Cu or Fe. The melt is poured into a cylindrical mold, cooled and a disk is cut for analysis.

This is common in many scrap yards where a material of considerable variety, both in composition and in shape and size, may constitute a lot. For these “alloys”, fundamental parameter XRF software programs are necessary, since no SRM will match the actual sample.

7.3.3 By Spark

This technique is most often used in the field to identify unknown or mislabeled material. The surface of the casting is cleaned by an appropriate means, and a small amount of material is sparked from the surface. The sparked particles are carried as an aerosol to an ICPOES. Alternatively, the light emitted from the sparking is carried by fiber optics to a dedicated spectrograph. The material is analyzed for a suite of elements, and the alloy is determined by computer matching with known alloys. With homogeneous samples and good calibration standards, quantitative results can be obtained.

Okochi et al. used the spark method and a spectrograph to determine 13 elements in Ni alloys, and later used spark ablation and ICPOES.

7.3.4 By Inductively Coupled Plasma Optical Emission Spectroscopy and Flame Atomic Absorption Spectroscopy

As with any wet chemistry technique, the most time-consuming step in the analysis is often the dissolution of the sample. This is particularly true for nickel alloys which are designed to be corrosion resistant. For this reason, most foundries prefer XRF as the prime technique for the analysis of their materials. For laboratories without XRF, ICPOES and/or FAAS is a good second choice.

The sample is dissolved by adding a small amount of water, then dilute aqua regia. This prevents passivation of the metal surface and speeds dissolution. In some cases HF may also be required. The sample solution may then be analyzed. If HF has been used, a corrosion-resistant nebulizer should be used for ICPOES, or the HF must be removed by fuming with HClO₄ or H₂SO₄. If the solution is taken to fumes, it should not undergo prolonged heating, otherwise refractory element oxyanions may form and precipitate. These can be difficult to redissolve.

Owing to the ability of ICPOES to analyze samples over wide concentration ranges, the technique is reasonably popular for the analysis of alloys for major, minor and occasionally trace elements. The limiting factor is the dissolution of the sample and the possible presence of HF in the solution, which will necessitate changing nebulizers.

FAAS does not present the same problems with respect to HF that affects ICPOES. With proper dilutions, major and minor elements can be determined. Kometani discussed the analysis of Cu–Ni–Sn spinodal alloys by FAAS.

7.4 Minor Elements in Nickel Alloys

For the purposes of this article, minor elements are those whose concentrations fall in the range 0.01–10%.

7.4.1 By Flame Atomic Absorption Spectroscopy and Inductively Coupled Plasma Optical Emission Spectroscopy

ISO 7530 describes the FAAS determination of Al, Co, Cr, Cu, Fe and Mn up to 4%, Si up to 2% and V up to 1% using an aqua regia dissolution with SrCl₂ added as an ionization suppressant. The sample solution could also be used for ICPOES analysis. Some alloys may require HF to achieve complete dissolution, in which case Si cannot be determined unless the dissolution is done in a closed vessel.

Peterson reviewed the FAAS analysis of alloys, including Ni alloys.

Papers have described the determination of B, Cr, Fe and Si and Co, Cr, Al, Ti, Mo, W, V, Fe, Nb and Mn. Ni has been determined, and also W.

Refractory elements are generally not well determined by FAAS, particularly W. This is owing to the formation of oxyanions in solution and the difficulty in breaking the metal–oxygen bond in the flame of the spectrometer.

ICPOES, however, can give reasonably good results for Hf, Mo, Nb, Ta, Ti, W and Zr. Some laboratories use Sc as an internal standard to improve accuracy. Sample dissolution in aqua regia or aqua regia–HF is used, depending on the alloy. If HF is used, a corrosion-resistant nebulizer must be used.
For levels below 1%, ICPOES is a good technique for the determination of Al, Ca, Co, Cu, Fe, Mn, Mg, Ti and V. These elements can also be determined by FAAS, but ICPOES has the advantage of rapid multielement analysis. There is no universal solvent for nickel alloys. For these elements, a mixture of aqua regia and HF, followed by fuming with HClO4, is a good starting point.

ICPOES is also very good for the determination of Ce and rare-earth elements in Ni alloys. ICPOES is also very good for the determination of Ce and rare-earth elements in Ni alloys. ICPOES has the advantage of rapid multielement analysis. Since trace elements can have a catastrophic effect on nickel alloys, there has been much reported in the literature, particularly with the development of ETAS.

ETAS is the method of choice for many trace elements (Se, Te, Bi, Pb, Tl, As, Sb, Ga, Al, etc.). A typical dissolution is done with HF–HNO3–H2O (1 : 1 : 1). It is best to prepare a fresh acid mixture for each shift.

To overcome problems with the dissolution of alloys, ETAS has been applied to solid chips. If this procedure is used, the chips are weighed on a microbalance and then placed in the atomizer. It is critical to place the chips in the same place each time, since the tube has a heat gradient. Because of the difficulties in manipulating the solid chips, this procedure has not achieved the same popularity as the dissolution–injection procedures.

Electrothermal atomization/laser-excited atomic fluorescence spectroscopy using solid chips was reported by Irwin et al. The authors indicated a long linear dynamic range and 1–4 orders of magnitude better sensitivity than conventional ETAS.

Recently, Hinds et al. determined Bi, Pb and Te by volatilizing the solid sample in an electrothermal atomizer and analyzing the vapors by ICPMS. The results were reasonable for Bi and Pb, but some problems were encountered with Te.

In using ETAS, it must be noted that untreated graphite tubes may form refractory carbides if elements such as W, Ta, Nb, Hf, Zr are present in the alloy. This will change the heating characteristics of the tube over time. Therefore, it is recommended that a coated tube, preferably a carbide-coated type, be used.

ISO 11437 describes the determination of Pb by ETAS. Hydride generation furnace AAS has also been used. Flow injection analysis speeds up the analysis compared with conventional ETAS. Various chemical modifiers must be used to complex the major components in the alloy (Ni especially) in order to form the hydrides.

Hydride generation AAS has also been used, and hydride generation ICPOES. FAAS can be used if a preconcentration step such as solvent extraction is introduced, or directly if the element has sufficient sensitivity, such as Ca or Zn.

The use of the high-temperature hollow-cathode technique appears occasionally. ICPES has been used to determine trace B in Ni alloys, although a separation step is required. Phosphorus is determined spectrophotometrically by extraction of the molybdate complex and subsequent reduction to Mo blue. ISO methods have been

developed for the Mo blue (ISO 9388) and the phosphovanadomolybdate complex (ISO 11400).

Boron may be determined spectrophotometrically using curcumin without distillation of boron as the methyl borate complex (ISO 11436). The sample must be digested in quartz vessels at a high enough temperature to decompose boron nitrides. The ISO method calls for fuming with a mixture of H₃PO₄ and H₂SO₄ in order to effect the decomposition. ISO 11436 describes the determination of B in Ni alloys by the curcumin spectrophotometric procedure.

Other applications of spectrophotometry are still encountered, but for most cases the use of AAS or ICPOES is more practical. De Pablos et al. determined Ga by fluorimetry.

Electroanalytical techniques such as polarography for Cd, voltammetry for Sn and differential-pulse anodic stripping voltammetry for Zn, Cd, Pb and Bi have been reported.

Spark-source mass spectrometry has been used for a number of trace elements, often those normally determined by ETAS. Isotope dilution mass spectrometry has been used to determine B.

XRF can be used for the upper range of trace-element concentrations (>0.002%), if the alloy standards match the samples. Below this nominal concentration, detection and accuracy suffer, owing to the heavy matrix.

Platinum is present in some superalloys. The sample, along with 15–20 mg of Te metal powder, is dissolved in a mixture of nitric, sulfuric and hydrofluoric acids. After boiling off the HF, Te is precipitated by the addition of SnCl₂. The Te precipitate collects the Pt. The precipitate is dissolved and Pt is determined by FAAS (La is added as an ionization buffer) or by ICPOES. Alternatively, the sample may be dissolved in a mixture of nitric, sulfuric and hydrofluoric acids, a small amount of copper is added and the Pt is cemented out with the addition of Zn powder. The precipitate is cleaned of excess Zn and is fused according to the nickel sulfide fire assay procedure or by the classical lead fire assay procedure and Pt is then determined as described in section 3.2.1.3.

Danilova et al. determined Ir in copper–nickel ores kinetically.

INAA has been used to determine Cl, P and S in alloys.

7.6 Carbon and Sulfur in Nickel Alloys

The conventional combustion IR instrumentation is the most common method for the determination of C and S in alloys. The analysis is usually done using chips or drillings.

7.7 Gases in Nickel Alloys

The conventional fusion GC instrumentation is used to determine O₂ and N₂. H₂ may also be determined in this way, but is not requested as frequently as O₂ and N₂.

INAA has been used to determine O₂ as has a discharge tube with a hot hollow cathode. Since high-nickel alloys are often melted in an inert atmosphere, that gas may have to be determined. Kon-dakova et al. used vacuum fusion mass spectrometry to determine Ar in alloys.

7.8 Recommended Methods for the Analysis of Nickel Alloys

Table 7 lists recommended and alternative ways to analyze nickel alloys. Owing to the large and complex family of nickel alloys, it is impossible to be more specific within the constraints of this article.

ACKNOWLEDGMENTS

The author thanks Lakefield Research Limited for its generous assistance regarding the literature survey. Thanks are also due to his colleagues at Lakefield and to Dr J Bozic and Dr St J.H. Blakeley of Inco Ltd., who provided valuable information.

Analytical methods for the determination of noble (precious) metals: ruthenium (Ru), rhodium (Rh), palladium (Pd), osmium (Os), iridium (Ir), platinum (Pt) and gold (Au) are presented in this article. Discovery, natural occurrence and main applications of the metals are described. Physical and chemical properties of noble metals are summarized.

The nobility and catalytic activity of precious metals are the main properties that allow their use in a wide variety of applications, e.g. as catalysts in various chemical processes, as autocatalysts, in the electrical and electronic industry and in jewellery. Recent applications of some platinum compounds (cisplatin and its derivatives) as anticancer drugs are important.

The large variety of complex matrices, wide analytical concentration range (from sub-ppb to >99.99%), low reactivity towards single chemical reagents, great chemical similarities (especially between the pairs Ru and Os, Rh and Ir, Pt and Pd), complexity of platinum group metals (PGMs) species in solutions and rates of reaction make the accurate determination of noble metals a difficult analytical problem. The use of direct instrumental methods is restricted owing to interferences caused by matrix elements and low analyte concentrations. Sampling, sample decomposition, separation and preconcentration are critical steps in the majority of analytical procedures used.

The choice of the digestion procedure used depends on the nature of the sample matrix and the analyte concentration. Fire assay (lead, iron, copper, nickel, tin or nickel sulfide as collectors), oxidizing fusion, acids treatment and chlorination are used to digest various materials. Precipitation, solvent extraction and chromatographic methods (ion-exchange and chelating resins, capillary electrophoresis) are applied to separate noble metals from associated base metals and to separate the individual precious metals. Preliminary isolation of ruthenium and osmium from the other noble and base metals, as well as from each other, by distillation or extraction in the form of RuO₄ and OsO₄, is often applied.

Spectrophotometric methods using the complexes with inorganic and organic reagents can be applied to the determination of precious metals at ppm levels. Atomic absorption spectroscopy (AAS) (flame and graphite furnace) is well suited to the determination of Au, Pd, Rh and Pt (ppm and ppb levels, respectively). Ultratrices (ppb and sub-ppb levels) of noble metals can be determined in a large number of complex matrices by inductively coupled plasma mass spectrometry (ICPMS) with or without separation and preconcentration steps. A wide range of PGM concentrations, from percentage to ppm levels, can be determined by X-ray fluorescence (XRF) directly in solid samples or after pretreatment procedures (fire assay, coprecipitation, chromatographic preconcentration). Nuclear techniques (mainly neutron activation) are favored for the determination of low (ppb and sub-ppb) levels of precious metals (high sensitivities for Au, Ir, Pd and Os) in geological samples. Voltammetric measurements in combination with sample preparation, including the transformation of noble metals into electrochemically active compounds, provide high sensitivity (ppm and ppb levels) for the determination. The use of standard reference materials is essential to check the accuracy of the results obtained by various analytical techniques.
1 INTRODUCTION

The noble metals are the elements from the eighth group of the periodic table: ruthenium (Ru), rhodium (Rh), palladium (Pd), osmium (Os), iridium (Ir) and platinum (Pt) (so-called PGM) and gold (Au). These metals are also called “precious metals”. The name reflects the economic value of the metals as well as their rare occurrence.

1.1 Discovery and Natural Occurrence

Gold is the only noble metal that has been known since prehistoric times. Ancient civilizations already recognized gold as a precious metal. Numerous legends, mythological stories, folk tales and even the bible show a special interest in gold. There were numerous attempts, in particular in the Middle Ages, to convert other elements into gold.

According to records platinum was known in the sixteenth century. It was used by the Indians of Ecuador to make small articles of jewellery. The first description of “platina” as a new infusible metal found in the mines of the Chocó district of New Granada, Colombia, was made by de Ulloa in 1748. The first scientific studies on platinum were carried out in Europe after Charles Wood brought some samples of native platinum to England in 1741. They were described in 1750 by William Watson. The name “platina del Pinto” (little silver of the Pinto River), derived from the first source of the metal, was replaced by “platinum” after establishing its elemental nature in the eighteenth century. Detailed histories of platinum were published in 1960(1) and 1982(2).

Palladium and rhodium were discovered by W.H. Wollaston in London in 1803 and 1804, respectively. They were isolated from the solutions remaining after dissolving crude platinum in aqua regia followed by precipitation of platinum as chloroplatinate. The names “palladium” and “rhodium” were given after the planetoid Pallas (discovered in 1802) and from the Greek rhodes (a rose) due to the red color of the rhodium compounds.

Two further PGMs were isolated by Smithson Tennant in 1804 from the insoluble residue remaining after the aqua regia treatment of crude platinum. They were called iridium after the Greek iris (a rainbow) as a consequence of the variety of colors of iridium salts, and osmium after the Greek osme (a smell) owing to the characteristic odor of the volatile osmium tetroxide.

The discovery of ruthenium by K.K. Klaus, professor of chemistry at the University of Kazan, Russia, in 1844 completed the list of PGM. Ruthenium was isolated from the residue left after the treatment of platinum ore from the Central Ural Mountains with aqua regia. Klaus ignited the residue with potassium nitrate and separated osmium by distillation in the form of tetroxide. The name of the element has its roots in Ruthenia, the Latin name for Russia.

The abundances of noble metals in the earth’s crust are at the level of 1 ppb for each of ruthenium, rhodium, osmium and iridium; 10 ppb for palladium; 5 ppb for platinum(3) and 3.5 ppb for gold.(4) Precious metals have also been found in meteorites.

The major sources of noble metals are in South Africa, Canada and Russia. They are all primary deposits, usually associated with ultrabasic rock formations and often with copper and nickel sulfide deposits.(5,6) They occur as native grains or in minerals such as sperrylite (PtAs2), braggite (Pt, PdNi)S, cooperite (PtPd)S, arsenopalladinite (Pd3As), stibiopalladinite (Pd3Sb), laurite (RuOs)2S, osmiridium (a syerskite with less than 60% of iridium and ca. 35% of osmium) and iridosmium (a nevyanskite with over 60% of iridium and ca. 20% of osmium). Ruthenium as a major constituent (7–15% in iridosmium and 9–14% in osmiridium) and small amounts of the other noble metals are associated with osmium and iridium deposits.

Native gold is present in sedimentary and igneous rocks in many parts of the world. It is also a minor component of base-metal ores, especially copper. Electrum is a specific gold and silver mineral (AuAg) containing 35.4% of silver. Gold and silver occur in nature as calvarite (AuTe2), sylvanite (AgAu)Te2, petzite (AgAu)2Te, krennerite (AgAu),Te, and nagyagite (containing gold, lead, antimony, sulfur and tellurium).

Since 1953 South Africa has dominated amongst the world’s producers of noble metals. The Merensky Reef of the Bushveld Igneous Complex in Central Transvaal in South Africa is the richest source of precious metals (Figure 1). The composition of the sources in the Merensky Reef is roughly 60% Pt, 25% Pd, 4% Rh and 11% Ru, Ir and Os. Native platinum, occurring in the basic igneous rocks in the Merensky Reef contains 70–90% of platinum and small quantities of the other noble metals and iron. Other large deposits of noble metals were found in Sudbury, Great Lakes Region, Ontario in Canada and in Noril’sk Complex of Siberia, Russia. The concentration of noble metals in Sudbury deposits is less than 1 ppm. South African noble metal ores consist of smaller amounts of copper and nickel than any other deposits. All other sources are primarily nickel and copper ores. Noble metals remain there only as by-products of nickel and copper mining. Minor resources of the PGM occur in other areas of the world. Colombia, USA (including Alaska), China and Western Australia are minor producers of noble metals.

1.2 Uses

Nobility and catalytic ability are the main properties that allow use of precious metals in a wide range of applications.(6,7) Platinum, palladium and rhodium are extensively used as components of automotive catalysts...
to reduce the emission of carbon monoxide, unburnt hydrocarbons and nitrogen oxides in exhaust gases. Platinum metals are also well established as catalysts in structural rearrangements and dehydrogenation of aliphatic hydrocarbons obtained by distillation of crude petroleum. Catalysts, in oxidation of ammonia to nitric oxides, in selective hydrogenation and dehydrogenation reactions for chemical intermediates in plastics, artificial fibers, rubber, pesticides, dyestuffs and pharmaceutical products provide other examples of the wide application of platinum metals in the chemical industry. There is a large demand for noble metals, in particular gold, palladium and platinum, from the jewelry industry.

Platinum, because of its low and temperature-dependent resistance, also finds numerous applications in the electrical and electronic industries, e.g. in thermocouples for temperature measurements, corrosion-resistant electrical contacts, electrodes, sensors for gas detection and optical data storage disks. It also has substantial use in the glass-making industry mainly for production of special glass and glass fiber. The importance of some platinum-containing compounds (cisplatin (cis-diaminedichloroplatinum(II)); carboplatin (cis-diammine(1,1-cyclobutaneicarboxylato)platinum(II)); iroplatin (cis-dichloro-trans-dihydroxo-cis-bis(isopropylamine)platinum(IV)) and their derivatives) as anticancer agents is rapidly increasing. Cisplatin was introduced into chemotherapy in 1978.

The main demand for palladium comes from the electrical and electronic industries. Multilayer ceramic capacitors for integrated circuits used, for example, in microcomputers, televisions, video recorders and compact disk players are made with the use of palladium. Palladium is also applied in the production of electrical contacts and conducting materials. Palladium alloys are extensively used in the chemical industry, mainly as chemical process catalysts. Jewellery and dentistry where gold is gradually replaced by less expensive palladium employ significant amounts of the world palladium supply as well.

A considerable increase in the use of rhodium in the world’s industry has recently been observed. The main demand for rhodium (ca. 73% of the total supply) comes from the production of autocatalysts. Rhodium as a component of platinum alloys is also used in production of
thermocouples, glass and glass fiber. The use of rhodium in the chemical industry in the production of nitric acid, hydroformylation of alkenes and carbonylation of methanol to yield acetic acid is growing.

The principal uses of iridium are related to its quite remarkable chemical and physical properties. Iridium is the most resistant of all metals to corrosion. It has a very high melting point (2443 °C) and it is the only metal that maintains good chemical properties in air at temperatures above 1600 °C. Thermocouples of pure Ir against 40% Rh–Ir are used to measure temperatures up to 2100 °C. Iridium-containing coatings of anodes in the electrochemical industry (e.g. in the production of chlorates) also have a wide range of applications. The production of crucibles suitable for growing oxide single crystals, such as gadolinium gallium garnet (GGG) and yttrium aluminum garnet (YAG), used in computer memory devices and in solid-state lasers represents the largest modern area of application of iridium. Iridium is suitable for making the crucibles in which single crystals of oxides can grow at temperatures above 2000 °C. Smaller, but essential demands for iridium come from other areas, e.g. medicine (for radioactive 192Ir in cancer therapy), dentistry and jewellery (for iridium-containing alloys).

The major uses of ruthenium are in the electronics and electrochemical industries. Chip resistors, resistor networks containing ruthenium thick film pastes and electrodes coated with ruthenium dioxide provide the main examples of industrial applications of the metal. Ruthenium is used to harden platinum and palladium alloys. Ruthenium compounds are widely applied as chemical catalysts. Recent investigations of ruthenium complexes as an alternative to platinum cancer inhibitors are of special interest. Cis-dichlorotetrakis(dimethyl sulfoxide)ruthenium(II) (cis-Ru(DMSO)4Cl2), cis-tetrakisamminedichlororuthenium(III) chloride (cis-[Ru(NH3)4 Cl2]Cl) and fac-trisamminetrichlororuthenium(III) (fac-Ru(NH3)3Cl3) have been recognized as highly active against some tumors with side effects lower than those from cisplatin.

Osmium alloys (with ca. 60% Os) are used as materials of extreme hardness, e.g. for instrument pivots. Osmium tetroxide is used as a strong oxidizing agent in organic oxidation processes and as a staining reagent for the microscopic examination of tissues.

Gold was primarily used in the jewellery industry and the investment world. For centuries dentistry has made use of gold. Gold compounds are used in medicine owing to their antirheumatoid activity. There has been a growing demand for gold from the electronics and metal industries both searching for chemically highly resistant alloys.

### 1.3 Physical Properties

Noble metals are silvery white (Pt, Pd, Rh, Ir), gray-white (Ru), bluish white (Os) and yellow (Au) metals. Some general physical properties of precious metals are listed in Table 1. High melting point and hardness (in particular of Os, Ru and Ir) distinguish PGM. All metals are ductile and malleable. They can be obtained in compact, sponge, powdered and blacks forms. The ability to absorb high volumes of gases, in particular hydrogen by palladium (900 volumes of hydrogen in 1 volume of palladium), and oxygen by platinum (100 volumes of oxygen in 1 volume of platinum) is a characteristic property of these metals.

### 1.4 Chemical Properties

The high ionization potential of precious metals results in their noble character. The metals exhibit high resistance to single chemical reagents, particularly to single mineral acids, hydroxides and active metalloids. Molten alkali and alkaline hypochlorite solutions attack all noble metals.

Oxygen attacks noble metals at high temperature. Osmium shows the strongest affinity for oxygen. Finely divided osmium is oxidizable at room temperature yielding the volatile tetroxide, OsO4, with its characteristic odor. Iridium exhibits the highest oxidation resistance. Ruthenium dioxide is formed at about 600 °C and converted to volatile RuO3 and RuO4 with further temperature increase. PtO2 and PtO3 formed during heating of platinum to a bright red heat in air can lead to its loss. Palladium dioxide formed at about 700 °C dissociates back to the free metal and oxygen at higher temperature.
Chlorine and fluorine attack all noble metals (osmium and ruthenium at about 100°C and 300°C, respectively; iridium above red heat; platinum and palladium slowly at room temperature) giving mixtures of simple chlorides and fluorides.

Noble metals exhibit numerous oxidation states in their compounds.\(^5\) Ruthenium and osmium can occur at the highest oxidation states (+VIII), corresponding to the number of periodic table group. The (+VI) is the highest oxidation state for Rh, Ir and Pt, (+IV) for Pd and (+III) for Au. Ruthenium, osmium and iridium can occur at the lowest ((−II) and (−I)) oxidation states. The most stable oxidation states are (+IV) and (+II) for Pt and Pd, (+III) for Rh, (+IV) and (+III) for Ir, Ru and Os.

Apart from simple binary compounds, such as oxides, halides and sulfides, noble metals form a variety of complexes with inorganic and organic ligands. \(\pi\)-Bonding ligands, such as CO, NO, \(\text{N}_2\), \(\text{CN}^\text{−}\), \(\text{SCN}^\text{−}\), PR₃, AsR₃ stabilize low metal oxidation states (−II, −I, 0, +I). Numerous complexes with halides, nitrogen, sulfur, oxygen and selenium as well as hydrides are known. Chloride complexes are of great importance in extraction and refining processes and also in the analytical chemistry of the noble metals. Strong complexes with oxygen are characteristic for ruthenium and osmium. The majority of the complexes of precious metals are kinetically inert.

All noble metal species occurring in solutions are extremely coordinated and complex. The metals can occur in numerous oxidation states and in many forms with different activity in a given oxidation state. Great chemical similarities (especially between the pairs: Ru and Os, Rh and Ir, Pt and Pd), the formation of compounds of similar composition and properties and the tendency for hydrolysis as well as formation of polynuclear complexes should be taken into consideration, in particular while aqueous solutions are examined. Strong reaction conditions, such as heating, high reagent concentration and long reaction time may be required for any ligand substitution, owing to the great inertness of many complexes. The complexity of the chemical properties of noble metals as well as the kinetics of the reactions in solutions cause serious problems in many analytical procedures. The availability of a standard solution containing a particular metal in a definite oxidation state and chemical form suitable for the analytical method being used is an important problem.

2 SAMPLE PREPARATION

2.1 Sampling

Sampling requires special attention in the analysis of noble metals. Standard methods of sampling can be used in the analysis of homogeneous materials, e.g. alloys, liquids, powders and so on. Noble metals, especially gold, often occur inhomogeneously in many matrices, e.g. in geological, environmental and biological materials. Powdering and the use of large sample size may sometimes be sufficient to ensure the representativeness of the sample in the case of minerals, ores and concentrates. Some preliminary operations, such as drying, crushing and grinding may be necessary. The formation of alloys, e.g. some electronic scrap with copper, lead and nickel, to produce homogeneous materials which can be sampled by standard methods is sometimes used. The history of the submitted sample must be taken into consideration prior to any reduction in weight or volume.

Special precautions are needed in sample collection and storage in the case of a readily reduced analyte (e.g. gold to elemental form) or an analyte easily oxidized to volatile compounds, (e.g. osmium to OsO₄). Careful treatment and storage of the sample may be necessary to avoid any changes in species of particular metals to be determined, e.g. in clinical samples.\(^8\) The determination of ultratrace of noble metals requires special attention, to avoid contamination during the sample preparation step. Sampling and decomposition steps may become the main sources of contamination.

2.2 Decomposition/Dissolution Techniques

The choice of procedure used to digest the sample of noble metals depends on the nature of the sample matrix and the analytes’ concentration.

Fire assay is the most popular procedure for isolation and concentration of noble metals from rocks, soils, sediments, minerals, ores and concentrates. Classical lead assay is the basis of the majority of digestion procedures used.\(^9\) Fire assay involves fusion of a sample at high temperature with a flux (\(\text{Na}_2\text{CO}_3\), \(\text{Na}_2\text{B}_4\text{O}_7\)), reducing agent (flour, starch) and collector (\(\text{PbO}\)). On fusion the analytes are extracted from a complex matrix into the lead button that is formed. The matrix elements react with the flux component to form a slag which is subsequently discarded. The lead button is placed on a cupel prepared from bone ash or magnetite. On heating to a temperature of about 800–850°C in an oxidizing atmosphere, lead oxide and nonnoble metal oxides are produced and absorbed into the cupel where a bead of precious metals remains. The precious metals alloy is usually treated with a mixture of acids to extract the analytes.

The extraction of noble metals from a large sample size of a complex matrix into a relatively small bead of a simple metals alloy is the main advantage of the fire assay procedure. However, success in the quantitative recovery of precious metals requires an experienced and skilled
assayer to optimize both flux composition and fusion conditions. Another drawback of the classical fire assay using a lead collector is that it does not provide efficient recovery for all noble metals. Quantitative collection can be achieved for gold, silver, platinum and palladium. The recovery of ruthenium, iridium and osmium is seriously affected by flux composition and experimental conditions. Losses of osmium due to the high volatility of OsO$_4$ can occur. Rhodium and iridium can be determined using the classical fire assay followed by cupellation using a gold bead. Silver is added to the charge when analysis of a sample containing gold, platinum and palladium approaching the detection limit (DL) concentration is carried out. Losses of iridium and ruthenium can occur when cupellation involving a silver bead is used.

The other fire assay collectors, e.g. nickel sulfide, iron–nickel–copper alloys and tin, were found to be capable of quantitative recovery of all precious metals. Nickel sulfide fire assay has recently gained popularity.\(^{(10-12)}\) Contamination due to large amounts of salts employed is a drawback of these sample pretreatment methods.

Wet acids treatment, alkaline oxidizing fusion and chlorination are the alternative digestion procedures used. The effectiveness of acids extraction depends on the chemical solubility of individual noble metals and sample composition.\(^{(13)}\) Palladium and rhodium are the only metals attacked by hot nitric acid and boiling sulfuric acid, respectively. Aqua regia is used for the dissolution of gold and platinum. Ruthenium, osmium and iridium resist the attack of a mixture of acids, including aqua regia. Mixtures of acids (HCl, HNO$_3$ and HClO$_4$) in wet-, dry- and high-pressure-ashing, were recommended for digestion of clinical, biological and environmental materials. Hydrofluoric acid is sometimes added to the extractant to attack silicate phases and facilitate the liberation of analytes. However, uncertainties in the quantitative recovery of noble metals limit the practical application of direct wet digestion procedures, in particular to geological and environmental materials. Alkaline, oxidizing fusion (NaOH, Na$_2$O$_2$) of the residue remaining after preliminary acid attack can be used to convert more resistant components into dissolved forms. Fusion with oxidizing flux can be effectively used to digest geological samples. The application of the method is restricted to small samples.

High recoveries (>90%) of all noble metals from the samples containing native metals, natural alloys and minerals can be achieved after quantitative conversion of analytes into chlorides that are easily dissolved in hydrochloric acid.\(^{(14)}\) Three types of chlorination procedure are used, “direct” chlorination in the presence of large amounts of an alkali chloride, “wet” chlorination at elevated temperatures and pressures in a sealed tube containing HCl and oxidizing agent, and “dry” chlorination by hot chlorine passing over the sample usually mixed with a small amount of NaCl in an open tube at 500–600°C. Dry chlorination has some advantages such as low concentration of salts and low blank levels. Moreover, large samples can be submitted for analysis and the level of contamination can be reduced. The use of bubbler apparatus avoids losses of volatile chlorides formed.

Platinum- and palladium-based alloys, containing up to 5% of the other noble metals undergo aqua regia treatment. Owing to the high volatility of osmium and ruthenium the decompositions must be performed in closed systems. The dissolution of alloys with a higher (≥10%) content of more resistant metals (Ru, Os, Ir) may be achieved at higher temperature and in high-pressure systems. Silver, if present in the examined sample, forms an insoluble residue.

### 3 SEPARATION AND PRECONCENTRATION METHODS

The great chemical similarities of the PGM, the low concentrations to be determined and the large interfering effects from matrix elements generally require separation and preconcentration steps prior to the determination. Chemical methods of separation using volatilization, precipitation and coprecipitation, solvent extraction, sorption and chromatographic techniques are applied to separate particular noble metals from their mixtures as well as from the base metals.

#### 3.1 Volatilization

In analysis of multicomponent noble metal samples the preliminary selective separation of ruthenium and osmium in the form of the volatile tetroxides, RuO$_4$ and OsO$_4$, is generally performed. Ruthenium and osmium are oxidized to Ru(VIII) and Os(VIII) and quantitatively transformed into tetroxides by treatment in acid solution with strong oxidizing agents, e.g. HClO$_4$ + H$_2$SO$_4$, KMnO$_4$, K$_2$CrO$_4$, NaClO, NaBrO$_3$. Both tetroxides can be isolated from the mixture of noble metals by distillation. Selective oxidation of osmium to OsO$_4$, which occurs in the presence of hydrogen peroxide or 5 M HNO$_3$, allows osmium to be isolated from ruthenium and from the other noble metals.

The form in which ruthenium and osmium are present in the solution examined affects the effectiveness of their conversion into volatile compounds. Chloride complexes require strong oxidizing conditions, e.g. the action of HClO$_4$ + H$_2$SO$_4$, to achieve quantitative oxidation to RuO$_4$ and OsO$_4$. Evaporation of the examined solution with sulfuric acid to remove hydrochloric acid prior
to distillation is often applied. Nitroso complexes of ruthenium exhibit high resistance to oxidants. They must be destroyed prior to any oxidation step.

Hydrochloric acid is most frequently used as the absorbing solution for volatile tetroxides. Ruthenium and osmium are reduced to various oxidation states (VI, IV, III and II) depending on the conditions used (hydrochloric acid concentration, temperature and reaction time). In 6 M HCl the RuCl₆⁵⁻ complex is the main reduction product of Ru(VIII). Reduction of Os(VIII) in hydrochloric acid proceeds slowly. Quantitative conversion of osmium into the stable OsCl₆³⁻ complex requires the solutions to be heated for a minimum of 20 min at 90–100 °C. Water, organic solvents (e.g. CCl₄, CHCl₃) or sodium/potassium hydroxide can also be used as absorbing media for both ruthenium and osmium tetroxides.

3.2 Precipitation and Coprecipitation

Chemical methods of separation based on the precipitation of sparingly soluble forms are used to isolate a single element or a group of elements from a mixture of metals. Silver is usually isolated from a mixture of noble metals by precipitation of silver chloride. Platinum, as a major component, can be separated by precipitation as the ammonium chloride (NH₄)₂PtCl₆. Platinum can also be separated from the other PGM by a hydrolytic method. At pH 6–8 all platinum metals form sparingly soluble hydrolysis products, whereas platinum remains in solution. The precipitation of palladium with dimethylglyoxime is widely used to separate palladium from the other metals.

Reduction to the elementary form under the action of numerous reductants, e.g. zinc, iron, copper, tin(II) chloride, hydrazine, formic acid and sodium tetrahydroborate, is the basis of separation of precious metals from a large number of base metals. The easier reduction of gold is used for its separation from platinum group elements. The use of oxalic acid, hydroquinone and nitrite as reductants leads to selective precipitation of gold from solutions containing the other noble metals. Platinum and palladium, in contrast to iridium and rhodium, are reduced to the elementary form and precipitated under the action of Hg₂Cl₂ or CuCl and during boiling with tellurium powder. Rhodium may be separated from iridium by reduction to the metal with Sb powder in hot H₂SO₄. Any precipitation of rhodium and iridium requires their preliminary separation from the other noble metals. Quantitative separation of particular noble metals may require a reprecipitation step owing to a tendency to occlude the other components present in the solution.

Reductive coprecipitation with a suitable collector is applied to separate noble metals from matrix elements and concentrate them to the level detected by instrumental techniques. Tellurium, selenium, arsenic, mercury and copper are most frequently used as collectors. Coprecipitation is effectively applied to quantitative separation of ultratrace amounts of noble metals from major and minor components of geological, biological and environmental samples. Coprecipitation with a tellurium collector following a sodium peroxide fusion was used to improve the concentration of Pt, Pd, Ru and Ir from geological materials.

3.3 Solvent Extraction

Solvent extraction is successfully used for separation of particular noble metals from their multicompontent samples, as well as from base metals. Halide (chloride, bromide and iodide) complexes form the basis of most of separation methods. Chelate complexes with organic reagents, e.g. α-dioximes, dithizone, carbamates, 8-hydroxyquinoline, formazans, thiourea derivatives, and ion pairs with high-molecular-weight amines are also used in many separation procedures. Neutral organic compounds containing sulfur (sulfides and sulfoxides) and phosphorus (e.g. triphenylphosphine (TPP), triethylphosphine oxide (TOPO) and tributyl phosphate (TBP)) effectively extract noble metals from various media. Solvating systems with oxygen-containing solvents are used widely. Extraction of Au(III) from 4–8 M HCl (HBr) as AuCl₄⁻ (AuBr₄⁻) into, for example, diisopropyl ether (DIPE), methyl isobutyl ketone (MIBK), ethyl or amyl acetate is often applied to isolate gold from various matrices.

Differences in the labile character of the platinum metals towards complexing and chelating agents, differences in the charge of particular metal species and inertness to hydrolysis may lead to different affinities to extractant and make up the basis of separation methods. Palladium chloride complexes are kinetically labile and readily react with a number of complexing agents at room temperature. The great inertness of platinum towards complexation often requires the solutions to be heated or labilizing agent to be added. Tin(II) chloride and iodides are often used to reduce Pt(IV) to Pt(II) which more readily reacts with many complexing agents. Extraction of palladium prior to formation of an extractable platinum complex (e.g. with dithizone) can be used for quantitative separation of both metals. Chloride complexes of Ru(IV), Ir(IV) and Os(IV) provide an example of highly extractable species through either the anion-exchange or hydration-solvation mechanism, whereas the extraction of Ru(III), Ir(III) and Os(III) is poor. The labile character of rhodium, in comparison with iridium, allows the separation of both metals in some extraction systems. Rhodium forms extractable complexes with, for example, 2-thiobenzothiazole, 2-thiobenzimidazole and diphenylthiourea while iridium...
remains in the solution. The high tendency of rhodium for hydrolysis may cause difficulties in obtaining a readily extractable complex.

Polyurethane foams were found to be effective extractants of noble metals from their thiocyanate solutions allowing selective separation of some binary mixtures, e.g. Rh and Ir,\textsuperscript{(25)} Ru and Rh,\textsuperscript{(26)} Os and Ru.\textsuperscript{(27)}

Separation of ruthenium and osmium by extraction of RuO\textsubscript{4} and OsO\textsubscript{4} (CCl\textsubscript{4}, CHCl\textsubscript{3}) is an alternative to the distillation procedure of separation for both metals. Osmium tetroxide can be directly extracted from the samples treated with aqua regia.

### 3.4 Sorption

Sorption methods are particularly convenient for concentration of small amounts of noble metals from solutions containing high concentrations of nonnoble metals. In some systems quantitative separation of precious metals from 10\textsuperscript{3}-fold quantities of accompanying metals (especially Cu, Fe, Ni, Co, Al, Mg and Ca) and concentration factors of ca. 10\textsuperscript{3} can be achieved.\textsuperscript{(28,29)} Inorganic and organic sorbents, as well as chelating resins have found application in concentration of noble metals. The sorption procedures can be performed in a batch or a column mode. Desorption of analytes by subsequent elution with suitable agents usually precede their determination by conventional analytical techniques. The metals can also be determined directly in the sorbent phase by physical methods applicable to solid samples (e.g. XRF). Some sorbents are destroyed by ashing at high temperature or heating with a mixture of perchloric, sulfuric and nitric acid before the determination of analytes by a selective analytical technique.

Sulfides of copper, mercury, lead, cobalt and nickel, oxides of aluminum, zirconium, tin and titanium, phosphates of zirconium and cerium, and insoluble ferrocyanides were examined as inorganic sorbents for noble metals. The low solubility of platinum metal sulfides in strongly acid media favored the sorption on sulfide collectors. Activated charcoal is also used to concentrate noble metals from parts per billion levels, in particular in analysis of water samples.

Resins impregnated with chelating ligands or chemically modified by the introduction of a functional group are widely used as chelating sorbents. High selectivity and efficiency are characteristic properties of this group of sorbents. Chelating resins containing a functional group with sulfur (e.g. dithiocarbamate, thiosemicarbazide, 2-thiobenzothiazole, benzylthiourea derivatives) and nitrogen (e.g. aliphatic amines and polyamines, heterocyclic nitrogenous ligands) have found special reference in separation and concentration of precious metals.

The POLYORGSM sorbents containing nitrogen–heterocycle ligands (heterocyclic amine and amidoxime groups) are highly selective for noble metals in the presence of base metals.\textsuperscript{(29)} They are especially efficient in direct group separation and concentration of noble metals from solutions of complex composition obtained after digestion of rocks, ores, minerals, alloys and industrial process solutions. Complete separation of noble metals in the presence of 50 g L\textsuperscript{-1} Cu(II), 100 g L\textsuperscript{-1} Ni(II) and Co(II) and 10–20 g L\textsuperscript{-1} Fe(III) was reported. Other base metals (e.g. Al, Ca, Mg, etc.) are not sorbed.

Preconcentration of ultratrace amounts of noble metals by sorption of some chelate complexes with, for example, 8-hydroxyquinoline\textsuperscript{(30)} and 1-(2-pyridylazo)-2-naphthol (PAN)\textsuperscript{(31)} on microcrystalline naphthalene has been reported.

### 3.5 Chromatographic Techniques

Ion-exchange chromatography is widely used for group separation of noble metals from base metals and for separation of precious metals from one another.\textsuperscript{(23,32)} Both cation and anion exchangers can be used for separation and preconcentration of noble metals. Strong chloride complexes formed in dilute hydrochloric acid constitute the basis of the majority of separation procedures. Anionic chloride complexes pass through cation-exchange columns while base metals which exist as cations under the conditions used are retained on the resins. Precious metals are retained by anion exchangers which do not absorb the base metals. A variety of different organic and inorganic agents (e.g. thiourea, mineral acids of different concentrations and at various temperatures) can be used for selective elution of particular metals. It should be noted, however, that quantitative conversion of a particular metal into a definite complex is required prior to the chromatographic separation step. Different forms of analyte present in the solution may behave quite differently during the chromatographic separation step providing difficulties in complete separation of the metals. The labile character of complexes towards aquation and the ability to change the oxidation state of the analyte are the drawbacks of ion-exchanging procedures. The retention of anionic complexes is additionally affected by their charge. Doubly charged complexes (e.g. PtCl\textsubscript{6}\textsuperscript{2−}, RuCl\textsubscript{6}\textsuperscript{2−}, IrCl\textsubscript{6}\textsuperscript{2−}) are strongly retained by the resins, whereas triply charged complexes (e.g. PtCl\textsubscript{6}\textsuperscript{3−}, RuCl\textsubscript{6}\textsuperscript{3−}, IrCl\textsubscript{6}\textsuperscript{3−}) are only weakly bound. Strong affinity of precious metals to the resin may cause difficulties in quantitative elution of analytes. In some systems, the use of differences in the strength of electrostatic interactions of particular complexes with the resin or labile character in the formation of cationic and anionic species allow separation of multicomponent mixtures of the metals.\textsuperscript{(23)} Dowex...
1-X8 provides an example of a strong anion exchanger exhibiting a high selectivity for noble metals.\(^{(33)}\)

The application of high-performance liquid chromatography (HPLC) using chelate complexes to separate and preconcentrate noble metals has gained popularity. 8-Hydroxyquinoline, PAN, 1-thiazolylazo-2-naphthol (TAN), 4-(2-thiazolylazo)resorcinol (TAR), diethylthiocarbamate (DDTC), 2-(6-methyl-2-benzothiazolylazo)-5-diethylaminophenol and thiourea derivatives are most often used as precolumn derivatization agents. The retention behavior and separation of analytes may be considerably affected by the composition and properties of the mobile phase (pH, the kind and the content of the organic solvents used). The combination of a preliminary group extraction with a subsequent chromatographic separation forms the basis of effective and rapid separation procedures.

\(N,N\)-diethyl-\(N\)′-benzylthiourea complexes of platinum, palladium and rhodium have been used effectively for separation of binary mixtures, \(\text{Pd} - \text{Pt}\) and \(\text{Rh} - \text{Pt}\), from platinum-based catalysts by thin-layer chromatography.\(^{(34)}\) Size-exclusion chromatography has been applied to investigate platinum metabolites in plants\(^{(35)}\) and gold drug metabolites in human blood.\(^{(36)}\) Platinum and palladium were both effectively separated from the samples of catalytic converters by capillary electrophoresis after conversion into chloride complexes under treatment with a mixture of HCl + HNO\(_3\).\(^{(37)}\)

### 4 DETERMINATION METHODS

Numerous chemical and instrumental techniques have been applied to the determination of noble metals in a wide range of sample types. The choice of a suitable detection technique is to a large degree limited by the concentration level to be determined. Great chemical similarities between precious metals provide potential sources of mutual interference in their determination by the majority of the methods used.

Classical (gravimetric and volumetric) methods can be applied to analysis of samples containing a sufficient quantity (from milligram levels) of analytes. Such methods are favored when establishing the accurate concentration of the standard solution is required.

Spectrophotometric methods using complexes with inorganic or organic agents can be applied to the determination of precious metals at the ppm level. Atomic absorption spectroscopy (flame and graphite-furnace) is particularly suitable for determination of gold, palladium, rhodium and platinum (parts per million and parts per billion levels respectively). Plasma sources (ICP and microwave-induced plasma (MIP)) with atomic emission spectroscopy (AES) or MS detection are recommended for analysis of multicomponent samples and where large concentration ranges are determined. ICPMS (together with isotope dilution (ID)) is particularly suited to the determination of ultratrace amounts (ppb and sub-ppb levels) of noble metals in a large number of complex matrices. It can be applied with or without separation and preconcentration steps. A wide range of precious metal concentrations, from percentage to ppm levels, can be determined by XRF directly in solid samples or after pretreatment procedures (fire assay, coprecipitation, chromatographic preconcentration). Nuclear techniques (mainly neutron activation) are favored in the determination of low (ppb and sub-ppb) levels of noble metals (high sensitivities for Au, Ir, Pd and Os) in geological samples. Voltammetric measurements in combination with sample preparation, including the transformation of noble metals into electrochemically active compounds, provide high sensitivity (ppm and ppb) of the determination.

#### 4.1 Classical Methods

##### 4.1.1 Gravimetric Methods

Chemical methods of analysis are most widely accepted for the determination of palladium. Precipitation of palladium with dimethylglyoxime has found the widest application among gravimetric methods used. It allows separation of palladium (in the range from a few milligram to 1000 mg) from the other noble metals, from medium quantities of base metals and from small amounts of gold. The selectivity of the reaction and the definite composition of the isolated precipitate are very important factors. A number of other oximes (e.g. \(\alpha\)-furilidoxime, \(\alpha\)-benzoinoxime, oxalenediamidoxime) have been examined as precipitation agents for palladium.

Gravimetric methods are relatively rarely used to determine other metals. Reduction in hydrogen to the elemental form is recommended for quantitative isolation of ruthenium, rhodium and iridium. Precipitation of sparingly soluble compounds with chosen, mostly organic, agents is also applied. However, the lack of specific reagents as well as difficulties in establishing the final composition of the isolated precipitate and coprecipitation are the main obstacles to developing methods suitable for quantification of particular metals.

Hydrolysis at pH 6–8 results in the conversion of platinum metals (except platinum) into sparingly soluble hydrated oxides. The hydrated oxides can be used as weighed forms for gravimetric determination after filtration and heating at ca. 450–600 °C. They may also be subsequently transformed into a metallic form by reduction in hydrogen. Hydrolytic precipitation allows platinum to be separated from the other precious metals. Platinum, in the form of Pt(IV), remains in solution...
under the conditions used. The precipitation of platinum in the form of ammonium chloroplatinate followed by ignition to platinum metal is a very old method used for separation of the metal. In the case of a larger proportion of associated precious metals, in particular iridium, rhodium and palladium, reprecipitation may be required. Chlorination to the anhydrous trichlorides and subsequent ignition (in air and hydrogen) into a metallic form can be applied to produce weighed forms for rhodium and iridium. Oxalic acid (pH 1–2), hydroquinone (0.1–1.2 M HCl) and nitrite are used for selective reduction of gold to a weighed metallic form in solutions containing platinum metals.

Noble metals belong to the acid sulfide group. Various inorganic (hydrogen or sodium) and organic (e.g. phenylthiosemicarbazide, thiobenzothiazole, thiophenol) sulfides have been proposed for precipitation of metals. Weighed forms obtained by coprecipitation of univalent thallium with the sulfides of the platinum metals, TlRu₂S₆, TlRh₂S₆, TlIP₃S₃, TlPd₂S₃, can be used for gravimetric determination. The method is limited to micro amounts of each metal.

A number of organic reagents (e.g. thionalone, thiourea, antipyrine derivatives, 2-thiobenzothiazol, benzidine) have been used to precipitate precious metals from various matrices. The complexes of ruthenium, osmium, palladium, rhodium and iridium with thionalone can be weighed. Partial reduction of Pt(IV) to Pt(II) and simultaneous oxidation of the reagent to dithionalone absorbed on the separated compound produce a mixed precipitate which limits the use of the reagent for gravimetric determination of platinum. Antipyrine derivatives, e.g. diantipyrilmethane, diantipyrilpropylmethane, form precipitates with osmium, platinum and palladium. Platinum, osmium and iridium can be precipitated with tetraphenylphosphonium and arsonium salts. Each platinum metal (except osmium) can be precipitated by benzidine.

Quantitative separation of noble metals in the form of sparingly soluble precipitates can be seriously affected by the form of the analytes existing in the solutions examined. Nitroso complexes present in the samples examined must be destroyed prior to any precipitation. Precipitation of ruthenium and osmium from the solutions of their tetroxides easily isolated from mixtures of precious metals by distillation is preferred.

A detailed discussion of gravimetric methods applied to the determination of noble metals has been presented.\(^{(38,39)}\)

### 4.1.2 Titrimetric Methods

Redox reactions, the formation of stable complexes and precipitation of sparingly soluble compounds, form the basis of titrimetric methods used for the determination of noble metals.\(^{(15,17)}\) The number of volumetric methods is relatively few compared with the gravimetric methods used. In general, the transformation of an analyte into a definite complex is required prior to the titration step. High inertness of noble metal complexes limits their use in titrimetric procedures.

The redox reactions Ru(IV \(\rightleftarrows\) III, IV \(\rightleftarrows\) VIII), Os(VIII \(\rightleftarrows\) IV, VI \(\rightleftarrows\) IV) and Ir(IV \(\rightleftarrows\) III) are the only ones used in titrimetric determination of ruthenium, osmium and iridium. Titanium(III), copper(I) chloride, hydroquinone, ascorbic acid and iodides, are used as titrimetric agents in reduction methods. Reduction of OsO₄ by iodides followed by a titration of iodine with thiosulfate ions provides an effective and rapid method for the determination of osmium at milligram levels. Interferences from the other platinum metals should be taken into consideration in the presence of strong reduction agents. Redox reactions are seldom used to determine palladium and rhodium, mainly owing to the high values of redox potential of the systems Pd(IV)/Pd(II), Rh(IV)/Rh(II) and low values of potentials of the Pd(II)/Pd(0) and Rh(III)/Rh(0) systems. Potassium permanganate and Ce(IV) sulfate are often applied to oxidize analytes to higher oxidation steps. The reaction Pt(II) \(\rightleftarrows\) Pt(IV) taking place under the action of a strong oxidizing agent is used for quantification of platinum.

Iodides, dithizone, thiourea, thionalid, DDTC, \(\alpha\)-nitroso-\(\beta\)-naphthol and thiobenzothiazol provide examples of inorganic and organic agents used in titrimetric methods resulting in the precipitation of sparingly soluble compounds. A titrimetric method using iodides as precipitation agent is often applied to the determination of palladium (Pd₂⁺) in alloys, catalysts and the other industrial products containing Pd, Pt, Au and Ag. The use of organic reagents generally allows lower amounts of analytes to be determined. Extractive titration with dithizone is an example of a method widely used for the determination of gold (at the 10⁻⁵% level) in ores, rocks, soils, waters and organic materials. Such a method was also applied satisfactorily to the determination of platinum in platinum–silver alloys.

Titration by using an excess of ethylenediaminetetraacetic acid (EDTA) followed by back-titration with mercury(II), zinc or lead can be applied to the determination of milligram amounts of palladium, platinum and rhodium in mixtures with some base metals, e.g. Fe(III), Th, In and Ta. The catalytic effects of noble metals on some redox reactions are the basis of titrimetric procedures. Spectrophotometry and potentiometry are most frequently used as detection techniques for titrimetric methods.
4.2 Spectrometric Methods

4.2.1 Ultraviolet/Visible Spectrophotometry

Spectrophotometric methods were historically the first spectroscopic methods applied to the determination of small amounts of noble metals. The considerable progress in use of spectrophotometry as an analytical technique, the availability of the instrumentation, the wide range of concentrations that can be determined and satisfactory precision and accuracy make the technique very popular for the determination of many elements, including precious metals. Although the number of other spectroscopic methods developed for determining precious metals has significantly increased, spectrophotometry is still a very useful technique, in particular for the determination of ruthenium, osmium and iridium. The number of papers devoted to the determination of noble metals by spectrophotometry is still high. A marked trend towards the application of the methods developed to the analysis of real samples can be noted. Recent progress in simultaneous analysis of binary mixtures of metals by applying derivative spectrophotometric measurements should be emphasized.

The determination of precious metals, particularly in multicomponent mixtures, is very difficult because of the mutual interference caused by their great chemical similarity and their ability to form complexes of a similar composition and properties. The low selectivity of the color reagents generally requires the separation of the precious metals from each other as well as from the interfering matrix. Solvent extraction and chromatographic techniques are most often applied to separate and preconcentrate the analytes prior to spectrophotometric detection. The integration of the detection technique with the chemical pretreatment step applied is essential. Numerous inorganic and organic reagents have been proposed for the determination of noble metals in various materials. In general, the methods involving organic chromogenic reagents provide better selectivity as compared with those employing inorganic ligands.

Colored complexes of precious metals with halide ions (chloride, bromide and iodide), thiocyanates and SnCl$_3^-$ ligands play an important role in quantitative methods of analysis. Complexes with SnCl$_3^-$ groups (SnCl$_2$ in HCl) are widely used for spectrophotometric determination of all platinum metals. The high lability of various forms which can occur in aqueous solutions and the tendency for the composition to change with even small changes in the reaction conditions present difficulties in obtaining reproducible results. The ligand and acid concentrations, temperature and reaction time affect the final composition of the complex obtained. The most labile complexes containing various amounts of Cl$^-$ and SnCl$_3^-$ ligands, gradually formed under addition of tin(II) chloride to the solution being examined, are characteristic of palladium. An osmium–tin(II) chloride complex (0.3 M SnCl$_2$, 2 M HCl) is the most stable among the complexes of platinum metals. The values of molar absorptivities (ε) are in the range from 2.4 × 10$^3$ L mol$^{-1}$ cm$^{-1}$ for osmium ($λ_{\text{max}} = 385$ nm) to 1.3 × 10$^4$ L mol$^{-1}$ cm$^{-1}$ for platinum ($λ_{\text{max}} = 403$ nm). An iridium–tin(II) bromide complex provides a higher sensitivity (ε at $λ_{\text{max}} = 402$ nm amounts to 4.96 × 10$^4$ L mol$^{-1}$ cm$^{-1}$) compared with the complex with SnCl$_3^-$ ligands.

Ruthenate (RuO$_4^{2-}$) and osmate OsO$_4$(OH)$_2^{2-}$ anions, obtained after alkaline oxidation fusion of powdered metals, can be used for the spectrophotometric determination of larger amounts of ruthenium and osmium. Molar absorptivities are equal to 1.74 × 10$^3$ L mol$^{-1}$ cm$^{-1}$ (465 nm) and 2.75 × 10$^3$ L mol$^{-1}$ cm$^{-1}$ (340 nm) for ruthenium and osmium, respectively. The selective determination of osmium in the presence of ruthenium can be carried out in iodide solutions.

Attempts to enhance the selectivity of the spectrophotometric methods by applying derivative spectrophotometry result in methods being developed that allow the determination of particular metals in mixtures. The resolution of overlapping absorption spectra of particular components by applying analogue or numerical differentiation is a characteristic property of the derivative spectrophotometric technique. The individual signal of particular analytes can be isolated from the examined mixtures by obtaining derivative spectra of the suitable order. The selective determination of metals using derivative spectrophotometry has been carried out for mixtures of ruthenium and osmium in the form of chloride and tin(II) chloride complexes; palladium, platinum and gold in chloride solutions; gold, palladium and platinum as bromide complexes and palladium and platinum in iodide solutions. Direct determination of ruthenium and osmium in aqueous solutions of their tetroxides has been presented. Derivative spectrophotometry was successfully used to determine platinum and iridium in reforming catalysts and platinum and ruthenium in Pt–Ru carbon supported catalysts for fuel cells after conversion of analytes into chloride and tin(II) chloride complexes, respectively.

Numerous organic reagents have been applied to the spectrophotometric determination of noble metals. Many of them contain sulfur as donor atom, e.g. dithizone, thiourea and its derivatives, p-dimethylaminobenzoyl-lidenerhodanine (rhodanine) and its derivatives, thio-Michler’s ketone, derivatives of dithio-oxamide (rubeanic acid), thiosalicylamide, dithiobenzoic acid, 1,4-diphenylthiosemicarbazide and 2-thiobenzothiazole. Complexes
of osmium(VIII) and palladium(II) with allylthiourea,\textsuperscript{55} platinum and palladium with dithizone\textsuperscript{56} and ruthenium(III) and rhodium(III) with octadecylthiocarbamate\textsuperscript{57} were used for simultaneous determination of particular metals in mixtures by derivative spectrophotometry.

A group of methods for determining noble metals are based on azo-compounds, e.g. PAN, 4-(2-pyridylazo)resorcinol (PAR), TAR, chloro- and bromodervatives of pyridylazocompounds, arsenazo III, sulfonitrophenol M, 2-(2-thiazolylazo)-5-diethyl-m-aminophenol (TAAP) and sulfochlorophenolazorhodanine.

Nitroso compounds, such as 1-nitroso-2-naphthol and 2-nitroso-1-naphthol, 5-nitrosodimethylaniline, p-nitrosodiethylaniline and nitroso-R salt have also been proposed as chromogenic agents for the determination of nitrosodiethylaniline and nitroso-R salt have also been.

The fact that more than one cation of the dye is involved in ternary systems containing cationic surfactants, mainly cetylpyridinium (CP) and cetyltrimethylammonium (CTA) ions.

Ion associates with basic dyes undergoing extraction or flotation preconcentration prior to spectrophotometric detection make the basis of very sensitive methods. Xanthene (rhodamine B and rhodamine 6G), triarylmethane (malachite green, brilliant green, crystal violet and victoria blue B) and azine (methylene blue and capri blue) dyes have been investigated as counter ions for the formation of sparingly soluble ion associates with anionic (chloride, bromide, iodide, thiocyanate and SnCl\textsubscript{3}\textsuperscript{--}) complexes of noble metals. The ion associates, existing in aqueous solutions as colloids or suspensions, undergo extraction or flotation when shaken with a nonpolar organic solvent.

The colored extract or solution obtained after dissolving a floated precipitate in an organic polar solvent (e.g. methanol, ethanol, acetone, dimethylformamide) form the basis of spectrophotometric measurement.\textsuperscript{58} In particular, the methods applying the flotation preconcentration steps provide great sensitivity for the determination (e in the range 2 \times 10\textsuperscript{5}–1.14 \times 10\textsuperscript{6}) owing to the high molar absorptivities of the dyes and the fact that more than one cation of the dye is involved in the formation of the sparingly soluble precipitate.\textsuperscript{59} Flotation–spectrophotometric methods, however, are nonselective and preliminary separation of analytes by another separation technique is generally required. Solvent flotation methods applying basic dyes for preconcentration of ruthenium and osmium for spectrophotometry have been reviewed.\textsuperscript{60}

4.2.2 Atomic Absorption Spectroscopy

AAS is widely used to determine noble metals in a large number of different materials: ores, rocks, minerals, concentrates, alloys, industrial products, biological and clinical samples, environmental samples, waste solutions and solids (including nuclear wastes). The technique can also be applied to the determination of impurities in high-purity noble metal alloys. It is particularly suitable for analysis of gold, palladium, rhodium and platinum.

Relatively poor DLs are obtained for iridium, ruthenium and osmium.\textsuperscript{61} Both flame (air–acetylene and nitrous oxide) and furnace atomizers were employed.

Sensitivities offered by flame atomic absorption spectroscopy (FAAS) at the most sensitive lines: 0.5–1 \mu g mL\textsuperscript{--1} Ru (349.9 nm, air–C\textsubscript{2}H\textsubscript{2}); 0.1–0.2 \mu g mL\textsuperscript{--1} Rh (343.5 nm, air–C\textsubscript{2}H\textsubscript{2}); 0.1 \mu g mL\textsuperscript{--1} Pd (244.8 and 247.6 nm, air–C\textsubscript{2}H\textsubscript{2}); 1 \mu g mL\textsuperscript{--1} Os (290.9 or 305.9 nm, N\textsubscript{2}O–C\textsubscript{2}H\textsubscript{2}); 6–10 \mu g mL\textsuperscript{--1} Ir (264.0 and 266.5 nm, C\textsubscript{2}H\textsubscript{2}); 0.5 \mu g mL\textsuperscript{--1} Pt (265.9 nm, N\textsubscript{2}O–C\textsubscript{2}H\textsubscript{2}) and 2 \mu g mL\textsuperscript{--1} Au (242.8 nm, N\textsubscript{2}O–C\textsubscript{2}H\textsubscript{2}) have been reported.\textsuperscript{62}

The sensitivity of AAS measurement is seriously hampered by mutual noble metal interferences and interfering effects from a number of common elements. The components of the aqueous solution examined (aqua regia, HCl) may also strongly affect the AAS signal. The use of nitrous oxide–acetylene flame allows some chemical interferences to be overcome. Buffers and modifiers (e.g. V, Cu, La) have been proposed to improve the atomization efficiency. The examination of a solution of the sample in a suitable organic solvent often results in enhancement of the sensitivity. MBK has found the widest application among the organic solvents tested for FAAS. Strong oxidants present in the samples examined lead to enhancement of the signal for ruthenium owing to improved transport and atomization efficiency of RuO\textsubscript{4} formed.

The use of the preconcentration steps provides the enhancement of the DLs offered by FAAS. A DL of 0.3 ng mL\textsuperscript{--1} Pd was reported for the system comprising a microcolumn packed with activated carbon fiber to preconcentrate the analyte.\textsuperscript{63} FAAS determination of platinum, palladium and rhodium in catalysts characterized by DLs of 5, 3 and 40 \mu g L\textsuperscript{--1}, respectively has been described.\textsuperscript{64} A DL of 1 \mu g mL\textsuperscript{--1} Pt in deactivated catalysts was reached.\textsuperscript{65} Concentrations of 0.1–50 \mu g g\textsuperscript{--1} Au were successfully determined in copper concentrates by combining reductive coprecipitation of gold using part of the matrix copper as collector.\textsuperscript{66} Improvement in the DL in the determination of gold (35 ng mL\textsuperscript{--1}) was achieved by combination of tubular flow Donnan dialysis with FAAS.\textsuperscript{67}

Graphite furnace atomizers offer sensitivities suitable for the determination of noble metals at submicrogram levels. Absolute DLs of 30 pg Ru, 10 pg Rh, 10 pg Pd, 2 pg Pd, 0.5 pg Au and 0.05 pg Pt were reported for the elements Ru, Pt, Pd and Au, respectively.\textsuperscript{68}
ca. 1 ng Os, 0.2 ng Ir, 30 pg Pt and 10 pg Au were reported. The mechanism of atomization of noble metals under an argon atmosphere using a graphite furnace atomizer was investigated. The “appearance temperature” (the lowest temperature at which atoms of particular elements are released from the surface of the atomizer into a vapor phase) as a function of the nature of the atomizer surface, the chemical form of the analyte present on the atomizer surface and the reaction leading to conversion of analyte into atoms were studied. The appearance temperature was in close agreement while using HCl or HNO3 media. The use of aqueous solutions of palladium, silver and gold or films of pure metals led to similar results. The appearance temperatures for aqueous solutions used were found to be lower than the melting point of some metals.

Because of serious interference from a number of elements, preliminary separation and preconcentration steps are generally applied prior to graphite furnace atomic absorption spectroscopy (GFAAS) detection. Solvent extraction, ion-exchange chromatography, sorbent exchangers and coprecipitation are widely used to separate noble metals from the interference elements and to preconcentrate them prior to GFAAS detection. Matrix extraction was applied to the determination of iridium, rhodium and ruthenium in high purity platinum. The AAS signals of Ir, Rh and Ru are strongly suppressed in the presence of large amounts of platinum. Preliminary, double extraction of platinum into isoamyl alcohol–MIBK provides results with satisfactory precision and accuracy for a minimum of 2 µg g⁻¹ Ir and Ru and 1 µg g⁻¹ Rh.

The interferences caused by the presence of the other platinum metals, gold, silver, nickel and iron in the AAS measurement of palladium, platinum and rhodium signals using a nickel sulfide fusion preconcentration step were examined. Strong interference of nickel on the determination of the three analytes was established. For a concentration of 250 mg L⁻¹ Ni, as representative of the average content after the fusion step, in a solution of 10% HCl containing 10 µg L⁻¹ Pd, 30 µg L⁻¹ Pt and 10 µg L⁻¹ Rh, the signals of palladium, platinum and rhodium were increased by 102%, 50% and 43%, respectively. The palladium signal was stable when the content of Ni was >250 mg L⁻¹. The platinum signal seemed to be stable at 25–100 mg L⁻¹ Ni and increased at 100–250 mg L⁻¹ Ni. The rhodium signal was least affected for all the nickel concentrations used. The presence of 10 mg L⁻¹ Fe caused 10% decrease in the signal for palladium and about 10% increase in the signals obtained for platinum and rhodium.

The mutual interference of PGM and gold when present in the proportions typically encountered in copper–nickel ores were studied after collective extraction of metals with a mixture of alkylaniline hypochlorite and petroleum sulfides and AAS examination of the extracts. It was established that palladium had no effect on the signals of platinum, ruthenium and rhodium up to a 500-fold excess. The 300-fold excess of palladium decreases the signal of iridium by not more than 10%. Platinum does not interfere with the determination of palladium and rhodium up to a 300-fold excess. A 200-fold excess of platinum only insignificantly decreases the signals of ruthenium and iridium. The presence of a 10–15-fold excess of rhodium does not interfere with the determination of the other PGM. The most serious interferences were observed from ruthenium on the absorption of iridium and from ruthenium and iridium on the signal of osmium. These interferences were apparent at a 15- to 20-fold excess of the metals. DLs of (µg g⁻¹): 0.001 Au, 0.005 Pd and Rh, 0.01 Pt, 0.02 Ru and Ir and 0.06 Os (5 g sample and an extractant volume of 5 mL) were reported.

The effects of copper and iron on the determination of platinum, palladium and rhodium by AAS were studied using the Polyorgs complexing sorbent to preconcentrate analytes from HCl solutions. Tolerable copper and iron concentrations amounted to 10 g L⁻¹ and 2 g L⁻¹, respectively.

Matrix interferences (NH4Cl, Al, Fe(III) and Cu(II)) on GFAAS determination of palladium, platinum and rhodium in some polluted biological materials were examined applying on-line sorbent extraction preconcentration with the use of bis(carboxymethyl)dithiocarbamate (CMDTC) chelates. DLs (ng g⁻¹) of 0.03 for palladium, 0.1 for platinum and 0.01 for rhodium were reached.

Chelates with ammonium pyrrolidinedithiocarbamate together with liquid–liquid extraction (LLE) using 4-methyl-2-pentanone were applied for separation and enrichment of palladium, platinum and gold from the human urine of unexposed people prior to GFAAS with Zeeman-effect background correction. DLs of 20 ng g⁻¹ for palladium and gold and 70 ng g⁻¹ for platinum were reported.

GFAAS is sufficiently sensitive for the determination of ultratrace amounts of noble metals in a large number of geological samples (rocks, minerals and ores), in particular when a suitable separation–preconcentration step is employed. Ion-exchange chromatography and coprecipitation with Se, Te and Hg as collectors are widely used to separate noble metals from matrix elements. Mercury is an ideal matrix for GFAAS because it is completely volatilized at low temperatures and causes no interferences.

An increase in the analytical signals of noble metals in the presence of organic substances (e.g. suspensions of chelating agents) was reported. The reduced sample preparation time and the decreased possibility of analyte losses through volatilization using solid sampling GFAAS
are promising. A range of solid sampling techniques such as spark ablation, laser ablation and glow discharge has been examined to interface with AAS for analysis of high-purity precious metals.\(^{(84)}\)

### 4.2.3 Atomic Emission Spectrometry

Simultaneous multielement capability and greater linear dynamic range are the main advantages of AES over the atomic absorption technique. However, the DLs offered by AES are poorer by up to two orders of magnitude compared with GFAAS. The DLs offered by inductively coupled plasma atomic emission spectrometry (ICPAES) at the most sensitive lines of particular noble metals are as follows: \(30 \text{ng mL}^{-1}\) Ru (240.272 nm), \(6 \mu\text{g mL}^{-1}\) Rh (343.5 nm), \(0.5 \mu\text{g mL}^{-1}\) Pd (225.585 nm and 228.585 nm), from \(0.5 \text{pg}\) to \(1 \mu\text{g mL}^{-1}\) Os (225.585 nm), \(0.03 \mu\text{g mL}^{-1}\) Pt (214.423 nm) and 0.02 and 0.03 \(\mu\text{g mL}^{-1}\) Au (242.795 nm and 267.595 nm, respectively).\(^{(62)}\) The technique is more suitable for the determination of iridium, ruthenium and osmium compared with AAS.

The capabilities of emission flame spectrometric detection of noble metals using different atomizers were investigated.\(^{(85)}\) DLs of \(0.001–0.01 \text{g t}^{-1}\) were reached using \(\text{N}_2\text{O–C}_2\text{H}_2\) flame. The effect of organic solvent (xylene, acetic aldehyde and nitrobenzene at a ratio of 4.5:4.5:1) introduced to the plasma on the ICPAES signals of iridium, rhodium, palladium and platinum has been studied.\(^{(86)}\) No mutual effects of the analytes have been found. An increase in the signal of iridium was observed in the presence of copper. DLs (\(\mu\text{g mL}^{-1}\)): 0.029 for Ir, 0.11 for Rh, 0.024 for Pd and 0.073 for Pt were reported. The effect of HCl/H\(_2\)O\(_4\) acids on ICPAES signals of silver, palladium and gold in the analysis of Ag–Pd and Ag–Pd–Au–Cu–Zn alloys decreased with increase in acidity.\(^{(87)}\)

Interfering effects of matrix elements may cause problems in the direct determination of low concentrations of analytes by the ICPAES technique. Base metals, (e.g. Fe, Cu, Ni, Cr, Ti, Mg and V) interfere with ICPAES signals of precious metals. In practice, the separation and preconcentration steps are generally applied prior to the detection of noble metals in rich matrices. Various separation and preconcentration procedures have been combined with ICPAES. Coprecipitation with CuS and 2-thiobenzothiazol followed by sorption on a suitable sorbent to separate copper was applied prior to the determination of Ir, Pt, Rh and Pd in copper-based minerals.\(^{(88)}\) DLs of \(5 \times 10^{-6}\%\) for Ir and Pt, \(5 \times 10^{-7}\%\) for Rh and 1 \(\times 10^{-7}\%\) for Pd were reported. Concentrations of gold (\(5 \times 10^{-8}\%\)), platinum and palladium (2 \(\times 10^{-7}\%\)) in natural waters were detected using a Thiopan-13 fibrous complexing sorbent to preconcentrate the analytes.\(^{(89)}\)

The interference of iron and manganese on the ICPAES signal of gold has been eliminated by using the chelating anion exchanger SRAFION\(^{(90)}\) NMRR (containing thiourea active groups bound to styrene-divinyl-benzene matrix) to separate and preconcentrate gold from rich sediments.\(^{(90)}\) A DL of \(0.9 \text{ng mL}^{-1}\) Au (242.795 nm) was achieved. The combination of flow injection systems incorporating microcolumns of Amberlyst A-26 and sulfhydryl cotton with ICPAES results in DLs of about 1 \(\mu\text{g L}^{-1}\) Au.\(^{(91)}\) The method was suitable for the determination of gold in waters and refinery effluent.

A 400- to 10 000-fold excess of Ca(II), Mg(II), Fe(III), Al(III), Zn(II), Ni(II), Cu(II), Mn(II), Zr(IV) to Ru(III) and Au(III) is tolerable while a poly(epoxy-melamine) chelating resin is used for separation and preconcentration of analytes at the ng mL\(^{-1}\) level.\(^{(92)}\) Preliminary separation of osmium by extraction of OsO\(_4\) is recommended to avoid common interferences (in particular from nickel and copper) in the AES determination of metal.\(^{(93)}\) The direct injection of OsO\(_4\) into a plasma torch provides an increase in sensitivity by a factor of 10 over conventional nebulization. Osmium when present in the (VIII) oxidation state gives the maximum atomic emission signal over a wide pH range.\(^{(94)}\) The reduction of osmium to lower oxidation states results in lower volatility of the element and in a decrease in the intensity of atomic emission signal. Osmium, in high noble metal content alloys, can be determined together with other noble metals (without distillation) after decomposition under the action of potassium tetrafluorobromate and conversion of the complex fluorides obtained into completely soluble forms.\(^{(95)}\) Direct ICPAES detection can be applied to monitor the levels of platinum complexes in blood after a chemotherapy treatment.\(^{(96)}\)

Some approaches to the application of microwave-induced plasma atomic emission spectroscopy (MIPAES) to the analysis of noble metal samples have been presented.\(^{(97,98)}\)

### 4.2.4 Inductively Coupled Plasma Mass Spectrometry

High speed, excellent DLs, wide dynamic range, the possibility of accurate multielement analysis and the unique capability of measuring isotopic ratios make the ICPMS technique the most promising for the determination of ultratrace levels of elements in complex matrices. ICPMS has found wide application to the determination of noble metals at ppb and sub-ppb levels in a large variety of geological, biological, environmental and industrial samples. A review of the application of ICPMS to analysis of noble metal samples has been published.\(^{(99)}\)

Direct application of ICPMS to quantification of noble metals in complex, in particular in geological and environmental, matrices is limited owing to the low...
concentrations determined, very often below the DLs offered, and matrix and spectral interferences. High salt concentrations can lead to suppression or enhancement of the ICPMS signal of analytes. Spectral interferences from ions and polyatomic groups, as well as from particular analytes, can occur owing to the limited resolution of the instrument used. Sample dilution, chemical separation, mathematical correction, calibration procedures such as standard addition and ID are used to eliminate interferences in ICPMS signals of noble metals.

The detection of precious metals at ppb and sub-ppb levels in complex matrices is generally preceded by a separation and preconcentration technique. The nickel sulfide fire assay is most frequently applied to separation and preconcentration of noble metals prior to the ICPMS measurement. Dry chlorination, acid dissolution and alkaline oxidizing fusion are also used. Direct sample introduction in the form of slurry, laser ablation and glow discharge technique provide the advantages of reduced sample preparation steps and lower amounts of chemicals used. However, the wide heterogeneity of the samples examined and the low concentrations to be determined seriously limit the use of direct sample introduction into the plasma.

The combination of nickel sulfide fire assay and ICPMS leads to the highest recovery of ultratrace amounts of noble metals in geological materials. Contamination due to the high amounts of salts employed is one of the drawbacks of the analytical procedure used. The effects of nickel and copper on the ICPMS signals of Pt, Pd, Ru and Ir were studied. The addition of 500 ppm of nickel (as nitrate) resulted in up to ten-fold enhancement in the analyte ion (at 100 ppb level) count rate. Approximately 5000 ppm of nickel suppressed the platinum signal by 50%. A quite different interference of nickel was observed while electrothermal vaporization was used for sample introduction into the plasma. Enhancement factors of 4.6 for palladium, 8.1 for rhodium and 9.4 for platinum were observed when 500 ppm of nickel was added to the solutions containing 100 ppb each of analyte. At higher nickel concentrations the enhancement factor decreased to, for example, 4.4 for palladium at 10000 ppm Ni. A smaller effect was observed from copper. Copper nitrate exhibited ca. 60% enhancement in the Pt signal compared with the chloride. The chloride is probably volatilized at temperatures below the vaporization temperature of the PGM whereas the nitrate is decomposed to the oxide and reduced to the metal. The use of electrothermal vaporization provides ca. 50% increase in the sensitivity of the Pt, Ru and Ir signals and 2.6% for Pd, compared with classical nebulization.

A comparison of aqua regia leaching and fire assay as separation and preconcentration methods for precious metals from rocks has been presented. Partial leaching of iridium, osmium, rhodium and ruthenium by aqua regia was reported. Good recoveries were obtained for gold, palladium and platinum. DLs for Ru, Pd, Ir and Pt in rocks in the range of 0.3–2 ng g⁻¹ were reported for ID ICPMS combined with alkaline fusion and tellurium coprecipitation. The anion-exchange separation step can be applied to eliminate potential isobaric interferences from some base metals on ICPMS determinations of Ru, Pd, Ir and Pt in geological materials. DLs of 0.2–0.5 ng g⁻¹ for the metals examined (1 g sample) were achieved. Large samples (250 g) of rocks containing nanogram per gram levels of noble metals were analyzed by combining dry chlorination and ICPMS. A review of the methods of separation of platinum metals from complex matrices (rocks, waters, plants), elimination of interferences, new introduction systems for ICPMS and measurement by ID has been presented.

The ICPMS technique is particularly suitable for osmium isotopic analysis. A unique opportunity to evaluate the isotopic ratios of osmium and rhenium is of great value in geochronology where the rhenium–osmium decay scheme (¹⁸⁷_Re → ⋯ → ¹⁸⁷_Os) is used to study the age of ore deposits and extraterrestrial samples. A DL below 100 fg Os was reached for microelectrothermal vaporization ICPMS determination of osmium in meteorites. Typical contents of 1000–2300 ppb of osmium and 220–260 ppb of rhodium in meteorites were estimated.

ICPMS is the most suitable technique for the determination of noble metals at ppb and sub-ppb levels in a large variety of environmental samples. In 1975 environmental concern about the growing contamination from motorization led to the introduction of platinum metals as components of automotive catalysts in order to decrease the emission of carbon monoxide, unburnt hydrocarbons and nitrogen oxides in exhaust gases. Soon, it was established that those metals were released from the catalysts into the environment in the form of nanocrystals attached to alumina particles. Enriched, as compared with crustal abundances, platinum metal contents in the environmental materials (e.g. water, plants, airborne particles, dust, soils, urban gullies, biotic materials and sediments) have been found. Difficulties in the determination of ultratrace amounts of noble metals, particularly in complex environmental matrices, seriously limit the number of the published results. In practice, published data concern mainly platinum, which is the major noble metal component in catalysts and, from the analytical point of view, is much easier to examine than, for example, rhodium.

Oxides of hafnium, ytterbium and tungsten cause spectral interferences in ICPMS determination of...
and platinum. In particular hafnium, which occurs in the earth’s crust at relatively higher concentrations than those of platinum, may enhance the platinum signal. The hafnium oxide signal overlaps the signals of the three most abundant Pt isotopes (\(^{198}\text{Pt} (32.9\%), \text{\textit{195}}\text{Pt} (33.8\%)\) and \(^{198}\text{Pt} (25.2\%))\). Hafnium should be removed from the samples before the detection of platinum. Extraction, ion-exchange chromatography, chelating resin and sorption on activated carbon were employed to separate platinum from interfering elements and to preconcentrate prior to ICPMS detection. The application of the ID technique to the evaluation of platinum concentration is a useful approach to eliminate the effects of interferents.

The small volume of effluents converted into aerosol by conventional nebulizers and the low efficiency of transport of the analyte into plasma are generally considered to be the weakest components in the successful coupling of plasma detectors to some pretreatment methods (e.g. liquid chromatography (LC)). The coupling of the thermospray system for the purpose of sample introduction into the plasma resulted in an increase in the sensitivity of the determination of platinum by a factor of 9.\(^\text{115}\) Direct electrospray ionization (ESI) of the eluent into the plasma allowing the introduction of the total volume of the eluent into the plasma has been used in the analysis of some anticancer drugs.\(^\text{116}\)

Analytical methods of determining platinum in environmental and biological samples have been reviewed.\(^\text{117}\)

Nanogram levels of gold in natural waters (DL of 0.19 ng L\(^{-1}\))\(^\text{118}\) and plant materials (DL of 0.04 ng mL\(^{-1}\))\(^\text{119}\) were detected by the ICPMS technique.

The application of ICPMS to detection of noble metals in clinical samples involves relatively simple sample pretreatment steps. In practice, sample dilution in order to lower the concentration of dissolved solids is sufficient. The level of analytes in the reagents used, especially in acids, and the purity of the vessels used, require special attention. Significant and unpredictable memory effects can occur, particularly when the vessels are used to determine the noble metals within different concentration ranges.

ICPMS has been found to be an ideal technique for monitoring the level of platinum in the body fluids and tissues of patients treated with cisplatin and other anticancer drugs.\(^\text{8,120}\) as well as physiological levels of noble metals in human body.\(^\text{121,122}\) The use of high-resolution inductively coupled plasma mass spectrometry (HRICPMS) for the determination of physiological levels of Rh, Pd, Pt and Au in blood and detailed discussion of mass spectral interferences caused by Pb, Sr, Cu and Zn which can occur in blood have been presented.\(^\text{123}\) The interfering effects of the elements examined (at \(\mu\)g L\(^{-1}\) and mg L\(^{-1}\) levels) on rhodium and palladium HRICPMS signals were recorded. The signals of gold and platinum were found not to be affected by spectral interference.

ICPMS was successfully used to determine platinum, palladium and rhodium in automotive catalysts.\(^\text{124–127}\) The technique could be directly applied to the determination of platinum.\(^\text{124}\) Instrumental correction was employed to determine palladium and rhodium owing to interferences from Pb\(^{2+}\) ions. The interferences from Zr and Y, present at appreciable amounts in modern autocatalysts, have been examined using glow discharge mass spectrometry (GDMS).\(^\text{127}\) The effect of sample size on the results of the determination of Pt, Pd, Rh and Ti using a microwave digestion procedure employing a mixture of HF, HCl and HNO\(_3\) or H\(_2\)SO\(_4\), H\(_3\)PO\(_4\) and aqua regia prior to the ICPMS measurement has been studied.\(^\text{125}\) A comparison of the results obtained for rhodium and platinum using liquid nebulization (DL of 0.02 and 0.04 \(\mu\)g g\(^{-1}\), respectively) and spark ablation (DL of 1.0 and 0.5 \(\mu\)g g\(^{-1}\), respectively) ICPMS has been presented.\(^\text{126}\)

4.2.5 X-Ray Fluorescence

XRF is widely used for qualitative and quantitative analysis of multicomponent samples. The high-speed, nondestructive nature of the analysis, the wide variety of the samples that can be examined (solutions, powders, alloys, etc.), the relatively simple sample preparation steps, the wide concentration ranges that can be determined (from parts per billion up to even 100%) and excellent precision are attractive features of the technique. XRF is widely applicable in analysis of noble metal samples.\(^\text{128,129}\) It can be directly applied to the determination of analytes at concentration levels from \(n \approx 10^{-4}\)\% to 70–80\%, or to detection of lower concentrations after the preliminary separation and preconcentration steps. Fire assay and sorption methods are favored to precede the XRF measurement. Dilution methods, internal standards or mathematical correction are used to eliminate matrix effects on the XRF signals of metals. The requirement for standards with the same chemical composition and physical properties limits the wide application of the technique to the analysis of real samples.

Problems relating to the representativeness and homogeneity of the geological samples for XRF analysis of noble metals, as well as sample preparation steps applied have been discussed.\(^\text{130}\) The effects of zinc and copper, the major matrix components in ores, rocks, minerals and concentrates on the determination of precious metals using a fire assay preconcentration step were investigated.\(^\text{129}\) It was found, that the presence of more than 200 \(\mu\)g of Ni or Cu caused a reduction in the signals of Ru, Rh and Pd by 10%. A 20% reduction was observed for Os, Ir, Pt and Au while 400 \(\mu\)g of base metals were...
present in the samples examined. The mutual effects of noble metals in their XRF signals can be neglected after selective extraction by Polyorgs™ X1-H as complexing sorbent.\(^{133}\) XRF was successfully applied to the determination of the elemental composition of platinum metal complexes.\(^{132}\)

Femtogram levels as an absolute DL of platinum were reported for XRF analysis of biological (blood, urine) and environmental (soil) samples.\(^{133}\) The influence of acids, bases and salts on the XRF signal of platinum has been studied. XRF was found to be suitable for monitoring platinum in biopsy tissues of patients treated with cisplatin.\(^ {134}\) The technique was successfully applied to the determination of gold in various types of samples, e.g. ores,\(^ {135–137}\) rocks\(^ {20,138}\) and jewellery.\(^ {139,140}\)

### 4.3 Catalytic Kinetic Methods

The catalytic effects of noble metals on a large number of various reactions form the basis of kinetic methods of analysis. The low DLs (ppb and sub-ppb levels) and the high precision of the results are the main attractions of kinetic methods. However, poor selectivity and the large effect of the chemical form of analyte present in the sample examined on the results obtained strongly restrict the application of the methods to analysis of real samples. Transformation of the metals into a suitable form (e.g. Os(VIII), Ru(III), Rh(III), Ir(IV)) is generally required prior to the detection.\(^ {141}\)

The catalytic effects of precious metals on the oxidation of organic substances, mainly aromatic amines and phenol derivatives, by various inorganic reagents (e.g. IO\(_4^-\), Ce(IV), H\(_2\)O\(_2\), hexacyanoferrate(II)), as well as the redox reactions in systems containing inorganic oxidants (IO\(_4^-\), ClO\(_3^-\), BrO\(_3^-\), MnO\(_4^-\), Ce(IV), Fe(III)) and reductants (I\(^-\), As(III), Sn(II)) form the basis of the majority of methods developed. The differing catalytic activity of particular metals in different media can provide the basis for their determination in each other’s presence.\(^ {142,143}\)

Osmium and ruthenium are most frequently determined on the basis of the catalytic effects of Os(VIII) and Ru(III) on a large variety of redox reactions.\(^ {144}\) Methods are generally developed for pure solutions of both analytes easily obtained by separation of ruthenium and osmium by distillation. Extraction and ion-exchange chromatography are also applied to separate the noble metals from a large excess of interfering base metals.\(^ {145}\)

Spectrophotometry and chemiluminescence are the detection techniques most often used for monitoring the rate of the reactions examined. Polargraphic methods based on catalytic currents recorded are also used to determine the metals.

### 4.4 Electrochemical Methods

Electrochemical methods are rarely applied to the analysis of complex noble metal samples. Difficulties in quantitative transformation of the analytes into electrochemically active compounds and severe interference from complex matrices limit the application of electrochemical methods to the analysis of real samples. Separation and preconcentration steps usually precede the final detection.\(^ {146}\)

Polarographic techniques are most widely applicable to the analysis of noble metal samples. Alternating current polarography, differential pulse polarography and anodic stripping voltammetry proved to be useful for determining sub-ppb levels of noble metals.

Adsorptive voltammetry based on catalytic reduction of protons by platinum–formazone (a condensation product of formaldehyde and hydrazine) complex provides a sensitive method for the determination of platinum in clinical\(^ {147–149}\) and environmental samples.\(^ {150}\) The technique was found to be suitable for the determination of natural levels of platinum (0.1–2.8 µg L\(^{-1}\)) and \(^ {149}\) in human blood and 0.5–15 ng L\(^{-1}\) in urine.\(^ {149}\) Large interfering effects from organic matrices can occur. A comparison of voltammetric results with those of GFAAS for platinum in clinical\(^ {147}\) and environmental samples\(^ {150}\) has been presented. Sub-nanogram per gram levels of platinum (DL of 21 pg L\(^{-1}\)) and rhodium (DL of 5.6 pg L\(^{-1}\)) in solutions containing formaldehyde and hydrazine in a H\(_2\)SO\(_4\)/HCl medium can be simultaneously determined.\(^ {151}\)

Adsorptive accumulation of the complexes of platinum and ruthenium with, for example, PAN on the surface of a hanging mercury drop electrode followed by reduction of the absorbed complex during the cathodic scan forms the basis of an extremely sensitive method (DL of 3.2 × 10\(^{-10}\) M Pt and 4.1 × 10\(^{-10}\) M Ru).\(^ {152}\) Different complexing ligands, various supporting electrolytes and the DLs achieved for the determination of platinum have been reviewed.\(^ {153}\) Detailed discussion of voltammetric methods for the determination of platinum metals has been presented.\(^ {154}\)

An alternating current polarographic method using the extraction of 8-thioquinolinates of Ru, Os and Ir allows their determination (DL of 2.2 × 10\(^{-13}\) M Ru, 6.1 × 10\(^{-7}\) M Os and 8 × 10\(^{-8}\) M Ir) in the presence of Pt(II), Ru(III), Au(III), Ag(I), Ni(II) and Cu(II).\(^ {155}\)

Coulometric methods applied to the determination of noble metals have been reviewed.\(^ {156}\) Coulometry was applied to the determination of platinum (in the range of 0.5–5 mg) in dead catalysts\(^ {157}\) and gold (>10%) in Au–Ag–Cu alloys.\(^ {158}\) Coulometric titration of platinum has been successfully used in the determination of large amounts of platinum (98–99.9%) in platinum alloys.\(^ {159}\)
4.5 Neutron Activation Analysis

The extremely high sensitivities offered by neutron activation analysis (NAA) make the technique particularly suitable for the determination of ppb and sub-ppb levels of noble metals in a large variety of materials. The analysis is accomplished by the production and detection of specific radionuclides of particular elements.

Thermal neutron activation of metals results in radionuclides of: $^{103}$Ru ($t_{1/2} = 39.8$ days); $^{104}$Rh ($t_{1/2} = 42$ s); $^{191m}$Os ($t_{1/2} = 14$ h) with its daughters $^{191}$Os ($t_{1/2} = 16$ day) and $^{190}$Os ($t_{1/2} = 31$ h). Radiogold daughter isotope, one of the products of thermal neutron activation of platinum ($^{198}$Pt ($n$, γ)$^{199}$Pt $\longrightarrow$ $^{199}$Au ($t_{1/2} = 3.15$ day), is used as a measure of platinum content. NAA of palladium is based on the reaction $^{109}$Pd($n$, γ)$^{110}$Pd ($t_{1/2} = 13.5$ h).

Gold can be determined with high sensitivity on the basis of the reaction: $^{197}$Au($n$, γ)$^{198}$Au producing $^{198}$Au nuclide ($t_{1/2} = 2.7$ day).

Direct application of NAA to the analysis of real samples is restricted owing to their complexity and the numerous interfering effects from matrix elements. In particular, the interfering effects can be critical in the determination of very low concentrations of analytes. Separation and concentration are often applied, either before or after the irradiation. Fire assay preconcentration, ion-exchange chromatography and coprecipitation with a suitable collector are most frequently used to separate noble metals from an interfering matrix.

Numerous neutron activation procedures for the determination of noble metals in a variety of geological, biological and environmental materials have been developed.$^{160–168}$ The combination of fire assay with NAA, particularly suitable for analysis of geological samples, has been studied by many authors. DLs of $10^{-3}–10^{-1}$ ppm of noble metals; $^{160}$ 0.2 (Os), 0.005 (Ir), 1.0 (Ru), 0.35 (Rh), 2.5 (Pt), 0.8 (Pd) and 0.001 (Au) (μg kg$^{-1}$) (100 g sample); $^{160}$ 0.002 (Rh), 0.025 (Pd), 0.018 (Pt), 0.0002 (Ir), 0.002 (Au), 0.020 (Os) and 0.2 (Ru) (mg kg$^{-1}$)$^{164}$ of noble metals in geological samples using fire assay and NAA have been reported.

All steps in the analytical procedure used can provide severe sources of errors. High heterogeneity of the examined samples and low concentrations to be determined require special attention during sampling and sample handling. The possibility of losses or contamination during the sample preparation steps requires special care. High purity reagents (e.g. acids of Suprapur grade or purified by sub-boiling distillation) are necessary when ultratraces of precious metals (ppb and sub-ppb levels) are determined.

Standards of an appropriate composition containing analytes in the definite form are required for calibration, especially when some analytical techniques are employed (e.g. LC and spectrophotometry). Spectral overlap and multiple interference (matrix suppression or enhancement) often occur. Estimation of the value obtained with the aid of statistics is very important in data assessment and presentation.

Analysis of certified reference materials (CRMs), interlaboratory comparisons, the use of definite analytical methods, comparison of the results obtained by different analytical techniques and recovery studies are used to check the quality of the results. Unfortunately, the use of CRMs in analysis of noble metal samples is considerably restricted owing to the limited number of materials available, their high costs and limited supplies. Geological materials, ores and concentrates provide the largest group of CRMs available. A majority of them have been supplied by Canada Center for Mineral and Energy Technology (CANMET).$^{13}$ The ore sample of certified values for all noble metals (SARM-7), is a product of National Institute for Metallurgy, Johannesburg, South Africa. The lack of CRMs for biological and environmental materials of different origin is a fundamental problem.

Calibration procedures, such as standard addition or ID, are recommended when the nature of the matrix is unknown or cannot be easily matched with the standards. Comparison of the results obtained by different analytical techniques is recommended. Interlaboratory studies may improve the quality of the determination.

5 QUALITY CONTROL AND ASSURANCE

Reliability of the results is the main concern in the analysis of noble metal samples. The accuracy assessment is of great importance in analysis of various samples containing analytes in different concentration ranges.

The choice of an appropriate analytical procedure is the fundamental factor affecting the quality of the results obtained. It should be noted that procedures suitable for the determination of noble metals in a specific matrix may not be applicable to their determination in a different material.

ACKNOWLEDGMENTS

The author expresses special gratitude to Dr. Jan Kryński from the Institute of Geodesy and Cartography, Warsaw, Poland, for designing the map of world sources of noble metals.

1 INTRODUCTION

Metals and other electronic conductors are troublesome for NMR experiments because of their strong interaction with RF fields (skin effect). It is just this effect that is used in RF electronics like NMR spectrometers to shield cables and circuits from unwanted electromagnetic radiation. Nevertheless it is also possible to obtain NMR signals from metals.

Even the earliest investigations showed dramatic consequences for impedance matching, line shapes, etc. [1]

As time domain NMR advanced to become a general tool in chemistry and solid-state physics, it appeared natural to study the behavior of nuclear spins in metals. Responses to common pulse sequences were discussed to form a basis for the evaluation of such experiments. [2,3]

It turned out that distributions of RF absorption and phase shifts within the samples spoiled almost any known experiment. Even for simple spectra the superposition of signals with different phases is a very inconvenient feature as no phase correction can restore true line shapes. More complicated pulse sequences that rely on $\pi$- or $\pi/2$-pulses suffer also from the distribution of RF amplitudes. Without model calculations no useful information could be extracted.

Facing all these problems it became common practice to avoid the skin effect as far as possible by using only fine metallic particles that are isolated from each other. This approach solves RF screening problems but by grinding every sample into fine powders one loses one of the most valuable properties of NMR – to obtain information without destroying the sample. Even worse, many metals show differences in their NMR signals by different mechanical treatments due to the ease of introducing defects into the respective crystal lattices.

In view of the strong influence of the skin effect on NMR measurements, one might ask whether it is possible to extract useful information by designing special experiments. A very interesting proposal used a series of a few systematically incremented single pulses to water that was both outside and inside a metallized glass tube. [4] It was shown that the thickness of the metallic films can be obtained by fitting the set of measurements with expected model functions.

or $^{19}$F, concentrations should therefore be higher than 1% and samples weighing 10 to 100 mg are recommended. The sensitivity to local interactions often makes it impossible to predict the visibility of NMR signals in unknown substances.

Nuclear magnetic resonance (NMR) is a spectroscopic technique which uses the magnetic component ($B_1$) of radiofrequency (RF) electromagnetic fields to excite nuclear spins which are subject to a static magnetic field ($B_0$). The resonance frequency is proportional to this field. Most stable elements possess at least one isotope with spin $I > 0$ and, hence, are observable by NMR. Magnetic field gradients make it possible to label spatial coordinates within a sample. Magnetic resonance imaging (MRI) uses this principle to reconstruct images from NMR signals. Skin effect enhanced imaging nuclear magnetic resonance (SEEING-NMR) derives its submicrometer resolution from the strong shielding properties of metals with respect to RF fields. Resonance frequencies of most isotopes are well separated from each other, making NMR an element-specific technique. Interactions of spins with their local environment lead to characteristic spectral changes that reflect the chemical state, the physical state or local geometry. The possibility of coherent manipulation and detection of spin states allows for an extreme flexibility in designing new and highly selective NMR experiments. Integrated signal intensities are strictly proportional to concentrations. The disadvantage of NMR is the small signal-to-noise ratio, especially for nuclei that have low resonance frequencies. Except for sensitive isotopes like $^1$H
2 HISTORY

Towards the end of 1945 Purcell, Torrey, and Pound discovered the first NMR signal at Massachusetts Institute of Technology.\(^5\) Only a few weeks later another group at Stanford – Bloch, Hansen and Packard – independently also found a nuclear resonance signal.\(^6,7\) The approaches of the two groups were so different that it took some time to realize that both had observed the same physical phenomenon.

NMR signals of metals were observed only 2 years later. Pound saw a Cu resonance which he identified as resulting from the copper wire of the RF coil that was used in his experiments.\(^8\) A little bit later, Knight discovered the typical large shift of the resonance of metals when he compared the line positions of copper metal and CuCl.\(^9\)

Soon after the discovery of metal resonances more systematic investigations were begun to learn more about the physics and chemistry of metals. Good examples are the study of diffusion in alkali metals\(^9,10\) and of hydrogen absorption in Pd.\(^1\) During these studies the pronounced effect of RF absorption in metals, the skin effect, complicated the experiments and the discussion of results.

The initial NMR studies were limited by the fact that only a few research groups in the world had the knowledge to build the necessary electronic equipment that was sensitive enough to detect the extremely small voltages induced by nuclear spins in metals.

3 NUCLEAR MAGNETIC RESONANCE PARAMETERS IN METALS

The most obvious macroscopic physical effect that occurs in NMR of metals is the above-mentioned screening of high-frequency electromagnetic fields. The electric component of the field generates strong currents at the surface of the metal. There are two important consequences of these currents.

The first is heat generated by the flow of current through the resistance of the metal. Rapid pulsing with complicated pulse sequences should be avoided or a big increase in sample temperature may occur. For the same reason it is not possible to do magic angle spinning experiments. In this standard procedure for solids to achieve line narrowing the sample is rotated very fast. The rotating metal “sees” the static magnetic field as an alternating electromagnetic field which also contains an electric field component. It is possible to melt a metal in this way. Another aspect of the heating is that the power is drawn from the transmitter. For the transmitter the conductive sample appears as an extra resistive load of the resonance circuit. This leads to a damping which not only changes the tuning and impedance matching but it also broadens and flattens the resonance curve as a function of frequency. As the same argument also holds for the receiver, the result is lower sensitivity with a poorer signal-to-noise ratio. It should be observed that this means that observed intensities depend not only on spin concentrations but also on the electric properties of the particular sample.

The second consequence of the surface currents during a pulse is that the generation of electromagnetic fields that compensate the external RF field inside the sample. The result is that the RF field that is used for exciting the spins decays very rapidly towards the inner of the sample. It is present only in a thin “skin”. Hence the name skin effect. The characteristic decay length, shown in Equation (1), is the skin depth \(\delta\)

\[
\delta = \left(\frac{\pi \mu_0 \sigma}{v}\right)^{\frac{1}{2}}
\]

where \(\mu(= \mu_0 \mu_0)\) is the magnetic permeability, \(\sigma\) is the electric conductivity and \(v\) is the RF frequency.

Typical values are \(\delta = 5–30\mu m\) for most metals and magnetic field strengths of modern NMR spectrometers.

Often it will be possible to approximate the sample as consisting of planar pieces where the magnetic component \(B_{10}\) of the applied RF field is parallel to the surface. This is the case, for example, for metallic foils or rods. Then the field \(B_1\) exhibits an exponential decay perpendicular to the surface. It is accompanied by a phase shift proportional to the distance from the surface \(x\) as shown in Equation (2)

\[
B_1 = B_{10} \exp\left(-\frac{x}{\delta}\right) \exp\left(i\frac{\pi x}{\delta}\right)
\]

where \(\delta\) is given by Equation (1). This depth-dependent phase shift makes it difficult but not impossible to interpret the line shapes observed in metals.\(^2,3\)

A third effect of induced currents in large metallic samples is that they produce a magnetic field which interacts with the static field. The consequence is forced mechanical vibration of the sample near resonance frequency. This in turn leads to induced currents in the observation coil that mimic a signal and might obscure the real signal. Low resonance frequencies (low magnetic field) favor mechanical oscillations. Hence, if this effect turns out to be important, higher magnetic fields should be used.

Also on a microscopic scale NMR signals are influenced by conduction electrons. The Knight shift \(K\)\(^8\) of the resonance frequency is very obvious. It is given by\(^11\) Equation (3):

\[
K = \frac{\delta \nu}{\nu_0} = \frac{8\pi}{3} \chi_p M \left|\psi_k(0)\right|^2_F
\]
where \(|\psi_k(0)|^2\) corresponds to the conduction electron density at the nucleus, \(x_p\) is the susceptibility per unit mass, and \(M\) is the atomic mass. Values for this shift can be found in tables.\(^{12,13}\)

Fluctuations of conduction electrons disturb the nuclear spins and are an efficient mechanism for relaxing them after initial excitation in the NMR experiment. Typical decay times \(T_1\) in metals at room temperature are often of the order of a few milliseconds or even shorter. A simple theory leads to the so-called Korrin of Korrin relation which relates the relaxation time \(T_1\) at temperature \(T\) to the Knight shift\(^{14}\) as shown in Equation (4).

\[
T_1K^2 = \frac{\hbar}{4\pi kT} \frac{\gamma_e^2}{\gamma_n^2} \tag{4}
\]

where \(\gamma_e\) and \(\gamma_n\) are gyromagnetic ratios of the electron and the nucleus, respectively. A more detailed discussion can be found in Slichter.\(^{15}\)

As the ground state of conduction band electrons is sensitive to applied magnetic fields it should be noted that at very low temperatures the effective field for the nuclei becomes a complicated function of external fields. This is known as the de Haas–van Alphen effect. Typically, the susceptibility shows oscillations as a function of the applied magnetic field. As seen above this will in turn change the Knight shift accordingly. This effect may easily change the Knight shift by some 10 ppm if the field is changed by 1000 ppm.\(^{16}\)

The majority of nuclei in metals have spin \(I > 1\). For them the interaction of the nuclear electric quadrupole moment \((eQ)\) with the local electric field gradient tensor \((\hat{V})\) is the main one. It leads to multiplets and modifies the positions of the \(2I\) lines. In first-order perturbation theory transition frequencies between energy levels with magnetic quantum numbers \((m - 1)\leftrightarrow m\) are given by Equation (5):

\[
v_m^{(1)} = v_0 - v_Q \left( m - \frac{1}{2} \right) \left( \frac{3 \cos^2 \theta - 1}{2} + \frac{1}{2} \eta \sin^2 \theta \cos 2\varphi \right) \tag{5}
\]

where \(v_0\) is the position of the unperturbed line, \(v_Q = (3V_{ZZ}eQ)/(\hbar 2I(2I - 1))\), \(\eta = (V_{XX} - V_{YY})/(V_{ZZ})\) is the asymmetry parameter, \(V_{XX}, V_{YY}, V_{ZZ}\) are principal axes components of \(\hat{V}\), and \(\theta\) and \(\varphi\) measure the polar angles of the field \(\vec{B}_0\) with respect to the principal axes frame \((X, Y, Z)\).

Note that for half-integer spins \((I = \frac{1}{2}, \frac{3}{2}, \ldots)\) Equation (5) predicts that the central line \((m = \frac{1}{2})\) is unperturbed. The orientational dependence often leads to extremely broad lines for the other transitions in the case of powders or polycrystalline materials. In those cases only the central line is observed which contains \(1/(2I)\) of the total intensity. For strong quadrupolar interactions second-order perturbation also shifts the central line. Equation (6) shows that for \(\eta = 0\) it is displaced by

\[
v_m^{(2)} = -\frac{v_Q^2}{16w_0} I(I + 1) - \frac{3}{4} \left( 1 - \cos^2 \theta \right) (9 \cos^2 \theta - 1) \tag{6}
\]

The situation is different if there is no electric field gradient present at the position of the nucleus for symmetry reasons. The transitions degenerate and the whole intensity is visible in spectra. To distinguish between these possibilities the technique of quadrupolar nutation\(^{17}\) can be used.

With small or vanishing electric field gradients the magnetic dipoles of neighboring atoms become a considerable source of line broadening and may dominate the line shape. This dipole–dipole interaction is also anisotropic and depends on the orientation of the line joining two nuclei with respect to the external magnetic field and their respective distances. Hence, line shapes due to dipole–dipole interactions can be calculated precisely if the geometry of the crystal lattice is known. Typical line widths due to this effect are \(1–10\) kHz.

### 4 APPLICATIONS

#### 4.1 Pure Metals

The first observation of a metal resonance by Purcell et al.\(^{9}\) where they saw the signal of the NMR coil itself, was soon followed by systematic studies of metals. One of these early experiments was devoted to looking at the line width in solid sodium at different temperatures.\(^{9}\) Surprisingly it was found that at 77 K the line width was \(2.5\) gauss while at 200 K it is narrower by a factor of 10. The latter is due to fast translational lattice diffusion of sodium atoms with jump rates in the kilohertz range even 170 K below the melting point. The fast motion averages partially anisotropic interactions. A similar behavior was found by studying the isotope \(^7\)Li in solid lithium.\(^{18}\) Line narrowing sets in above \(230 K\). A more detailed study on the same system showed that this motion is present up to the melting point and is described by a simple Arrhenius behavior with an activation energy of \(E_a = 55.2\) kJ mol\(^{-1}\).\(^{10}\)

Another physical quantity studied in alkali metals is the volume dependence of the Knight shift.\(^{19}\) The variation of the volume was achieved by applying pressures between 0 and 10 kbar. The effect is easily observable and amounts to \((\Delta K/K)/(\Delta V/V)\) values of +0.15, +0.1, −0.3, and −1.7 for Li, Na, Rb, and Cs respectively.

The sensitivity of the line shape and line position to changes in the local environment of the metal nucleus as well as to the electronic band structure makes it a valuable tool for analytical work. A textbook example for
this type of application is an early study of copper. It was found that filings gave a signal that increased by a factor of 2.5 after annealing. Partial annealing or etching led to intensities in-between. Cold work introduces mechanically dislocations and crystal defects. This, in turn, distorts cubic symmetry and electric quadrupole interaction dominates the spectra. Except for the central transition all other are broadened beyond detectability. For $^{63}\text{Cu}$ ($I = \frac{3}{2}$) the intensity contained in the central transition only is 0.4, in excellent agreement with the assumption that filing distorts the copper lattice to such an extent that every nucleus experiences a strong electric field gradient due to loss of symmetry in its immediate environment. Careful calibration of intensities allows for a quantitative determination of lattice defects.

4.2 Alloys

Intensity changes of the observable magnetization are also the basis for studies of alloys and the observation of alloying processes. Again, lowering the local symmetry is the reason for these changes. The effect is typically much bigger as compared to lattice defects due to direct electronic effects between the different metal atoms. For nearby neighbors the electric field gradient may become so large that the second-order shift of the central line (Equation 6) is sufficient to shift it beyond visibility. This creates an “all-or-nothing” effect and the intensity approaches zero at higher concentrations. NMR signals from copper–zinc and copper–silver alloys were the first that were interpreted in this way. The study of the concentration dependence of $^{63}\text{Cu}$ signals for both alloys led to the conclusion that foreign atoms located in the first and second coordination shell (18 atoms) are able to wipe out the signal of a copper nucleus.

In aluminum–zinc alloys the effect on $^{27}\text{Al}$ signals is much smaller and resembles the behavior of mechanical defects in copper. Only a reduction of the central line is observed and with higher concentrations of foreign atoms it approaches a fraction of 9/35, the intensity of the central transition alone. Obviously, the smaller number of electrons around the aluminum nucleus is not able to create an electric field gradient that is sufficient for a big second-order effect. NMR studies on dilute aluminum alloys can be found in Stiles and Williams. Later $\text{Cu-Zn}$, $\text{Cu-Ag}$, $\text{Cu-Ga}$, $\text{Cu-Au}$, $\text{Cu-Pd}$, $\text{Cu-Ni}$, $\text{Cu-Mn}$, $\text{Cu-Ge}$, $\text{Cu-Pt}$, and $\text{Cu-Fe}$ alloys were studied over the concentration range of 10–4500 ppm noncopper atoms. A standard-addition technique is proposed to quantify the amount of impurities in industrial copper.

The method was also used to follow the progress of mechanical alloying of Cu and Zn in a ball milling process. Owing to their slightly different Knight shifts a quantification of unalloyed copper, $\alpha$-$\text{Cu(Zn)}$ (fcc), and $\beta$-$\text{Cu(Zn)}$ (bcc) is possible by deconvolution of the $^{63}\text{Cu}$ signal.

Studies of Knight shifts and longitudinal relaxation rates have been used to determine local order and long-range disorder in several amorphous metals (metallic glasses). It was found that nickel–boron alloys show no different local electronic structure in amorphous phases than in the crystalline state. In more complex Pd–Cu–P systems similar studies exhibited structural differences between crystalline and amorphous forms. In the latter phosphorus atoms are preferentially coordinated by Pd. Long-range disorder was studied by relaxation measurements in MoRuP glasses and in NiPB.

4.3 Liquid Metals

The above-mentioned study of $^7\text{Li}$ at several temperatures and magnetic field strengths includes also liquid lithium. It is found that in liquid lithium a Korringa relationship (Equation 4) holds. This proves that conduction band electrons dominate relaxation of metal nuclei also in the liquid state. In contrast to the solid, molecular motion of metal atoms does not result in fluctuating fields that give rise to significant spectral densities around 10 MHz and, thus, does not contribute to spin-lattice relaxation.

A large variety of NMR and other studies of a very large number of different liquid alloys are reviewed and discussed in a more recent article. While this theoretical article is not directly interesting in the context of this encyclopedia, it points to a very large database of NMR parameters that may be very helpful for future analytical work.

4.4 Ferromagnets and Superconductors

Strongly magnetic materials require different techniques to produce NMR signals. Internal fields exist in ferromagnets. In some cases these hyperfine fields even exceed the strongest fields that are used in NMR today. In pure cobalt the nucleus experiences a field of $21.34 \text{T}$ whereas the respective field strength in iron is $33 \text{T}$. Rather than putting these metals into NMR magnets it is much better to utilize their internal fields to produce the resonance signal. This avoids not only further complicated physics but also eliminates serious mechanical problems due to magnetic forces in the case of bigger samples. For the excitation of NMR signals in strong ferromagnets it has to be taken into account that the RF field is also strongly amplified, by a factor of 1000 in the case of cobalt. It was found that the only spins observable are located at domain walls and the signal
of processing nuclear spins is greatly amplified by the hyperfine field.\(^{32}\) This signal enhancement breaks down if strong external fields are applied that cause magnetic saturation.

The above examples represent pure metals with local cubic symmetry. Hence, the hyperfine field is essentially the same at all nuclei and reasonably sharp lines are observed. If the structure becomes more complicated, NMR spectra reflect the distributions of hyperfine fields. These may extend over a range of several tesla and NMR frequencies that span several tens of megahertz. In these cases detection has to be done by spin echoes and intensities determined individually point by point at several resonance frequencies, as typical NMR probeheads possess bandwidths of not more than a few hundred kilohertz, to obtain a reasonable signal-to-noise ratio. The interpretation of NMR spectra as a distribution of hyperfine fields was used to deduce the distribution of coordination numbers in amorphous CoBSi alloys.\(^{32}\)

Isolated magnetic atoms in a nonmagnetic matrix can be studied by a technique called satellite NMR.\(^{33}\) This method observes the resonance of matrix atoms. If distances between matrix and impurity atoms are well-defined, a series of weak lines at a distance from the strong pure matrix signal appear. The shift is a direct consequence of the magnetic field of the impurity. Though experimentally demanding, satellite lines were identified and explained in terms of coordination shells in a number of doped coppers (Sc, Ti, V, Cr, Mn, Fe, Co, Ni).\(^{33}\)

Early NMR experiments on metallic superconductors were carried out in parallel with the appearance of the Bardeen–Cooper–Schrieffer theory of superconductivity.\(^{34}\) The experimental results were inconclusive with respect to the validity of this theory, which assumed spin pairing. While longitudinal relaxation data of Al supported it, Knight shift measurements on Hg and Sn pointed clearly to residual electron paramagnetism even at \(T = 0\) K.\(^{35–37}\) Careful studies of ultrapure Al layers\(^{38}\) resolved the puzzle by showing that the Knight shift is due to small paramagnetic impurities like oxygen and can be used to quantify these. According to Equation (3) the impurity’s finite \(\chi_p\) at \(T = 0\) K can produce a Knight shift under these conditions.

\(^{17}\)O studies of many high-temperature superconductors\(^{39}\) helped to identify the role of different types of oxygen for superconductivity.

### 4.5 Metallic Interfaces

As RF fields penetrate a few micrometers into a metal, NMR offers the possibility to study destructionless buried metallic layers and interfaces. SEEING-NMR, which is described in more detail in the next section, uses the skin effect for spatial resolution below 1 µm and delivers separate NMR spectra as a function of depth.

In ferromagnetic layers the huge gain in intensity allows the detection of extremely thin layers and even monolayers if low temperatures (1 K) are used to enhance the population difference of nuclear energy levels. The different environment of interface atoms from those in the bulk leads typically to drastically changed hyperfine fields. Because of its outstanding sensitivity \(^{57}\)Co in ferromagnetic phases was the prime target to investigate local structure, symmetry, surface roughness, and strain of metallic interfaces by NMR. Application of magnetic fields in different directions may help to assign signals from anisotropic structures and often sharpen the lines through removal of large-scale magnetic inhomogeneities by magnetic saturation of the sample. In Co/Cu and Co/Co multilayers differently coordinated interface atoms were clearly identified.\(^{32}\) By modeling the spectra, quantitative information about mixing across the interface was obtained for both systems. Similar studies on Fe/V, Co/Sb, and Fe/Mn multilayers revealed several details.\(^{32}\) In Fe/V mixing takes place over three to five atomic layers depending on the method of preparation.\(^{35}\) At the interface of the Co/Sb system nonmagnetic Co and the compounds CoSb\(_2\) or CoSb\(_3\) were identified.\(^{32}\) In Fe/Mn random mixing of the two phases takes place over 1.5 nm.\(^{32}\) Systems like Co/Ru and Co/Cr\(^{40}\) where the two metals can form solid solutions show, as expected, thick regions with interdiffusion. Even more complicated is the behavior of Co/Fe systems. These elements can form intermetallic compounds, and layer-thickness-dependent segregation into intermetallic and Co-rich phases was observed.\(^{40}\)

In Co/Cu, Co/Ni, and Co/Pd multilayers strain due to crystallographic mismatch was determined by using the fact that the line shift is proportional to a volume change and, hence, strain.\(^{32}\)

### 5 Method Development

Responses of the nuclear magnetization in metals to common pulse sequences were discussed to form a basis for the evaluation of such experiments.\(^{2,3}\)

It turned out that distributions of RF absorption and phase shifts within the samples (Equation 2) spoiled almost any known experiment. Even for simple spectra the superposition of signals with different phases is a very inconvenient feature as no phase correction can restore true line shapes. More complicated pulse sequences that rely on \(\pi\)- or \(\pi/2\)-pulses suffer also from the distribution of RF amplitudes. Without model calculations no useful information could be extracted.
Facing all these problems, it became common practice to avoid the skin effect as far as possible by using small metallic particles that are electrically isolated from each other. But by grinding a sample into fine powders, one loses one of the most valuable properties of NMR—the ability to obtain information without destroying the sample.

SEEING-NMR solves line shape and phase problems by looking at the response of a series of pulses with increasing pulse lengths. This is called a nutation experiment. Different nutation frequencies that belong to different RF field strengths and, hence, different depths are extracted by a Fourier transform with respect to the pulse length. As every pulse also excites the whole spectrum, the experiment is actually a two-dimensional (2-D) NMR experiment. The final 2-D spectrum represents a series of normal NMR spectra containing all of the above-discussed chemical and physical information about the metal separated with respect to depth. Spatial resolution may be as high as 100 nm. The observable depth is about twice the skin depth (Equation 1).

SEEING-NMR spectra of deuterium absorbed in Pd revealed a higher concentration of \(^2\)H just below the surface.\(^{41}\) Application of this technique to electrochemically produced Cu/Ag multilayers showed that the Knight shift of deposited copper is different from that in the annealed Cu that served as a base material for deposition. The amount of disorder in the copper was estimated.\(^{42}\) Analysis of the observed intensity profile of the \(^{63}\)Cu resonance perpendicular to the surface quantified the variation of layer thicknesses over the sample and elucidated the correlation of thicknesses among different layers.\(^{43}\)

A logical extension of this technique is the addition of magnetic field gradients during the experiments to achieve spatial resolution in the other two directions parallel to the surface.\(^{44}\) Work in this field is currently in progress.

THERMAL EVOLUTION METHODS FOR C, S, O, N AND H IN IRON AND STEEL ANALYSIS

Dennis A. Lawrenz and Joel Mitchell
LECO® Corporation, St. Joseph, USA

1 INTRODUCTION

Thermal evolution methods have been used for many years to determine the carbon, sulfur, oxygen, nitrogen, and hydrogen contents of iron and steel. Thermal evolution refers to a method for measuring the chemical composition of iron and steel whereby a sample is subjected to a process of heating, combustion, or fusion. These methods are considered to be destructive analyses. Combustion techniques are employed for the determination of carbon and sulfur, while inert gas fusion techniques are used for oxygen, nitrogen, and hydrogen. Hydrogen may also be determined via hot extraction. Analytical instrumentation based on thermal methods is commercially available.

2 HISTORY

For most of the twentieth century, thermal evolution methods have been used to determine carbon, sulfur, oxygen, nitrogen, and hydrogen in iron and steel products. Beginning early in the century, carbon was determined through the use of gravimetric methods. Samples were placed in an oxygen-purged resistance furnace. The combustion of carbon released from the sample formed carbon dioxide, which could be absorbed onto soda-asbestos. The carbon content of the sample was then determined by the mass gain of the soda-asbestos. This procedure is commonly referred to as the gravimetric carbon method. Likewise, sulfur was determined by combusting a sample in oxygen using a resistance-heated furnace followed by absorption of the oxides of sulfur. The sulfur oxides then reacted with potassium iodate and potassium iodide to produce a colored solution. This solution was subsequently measured by either a color comparison or a titration technique. During the 1960s, high-frequency (HF) induction furnaces began to replace resistance-heated furnaces for both carbon and sulfur determinations. HF induction furnaces were the furnaces of choice in the 1970s for the combustion of steel and iron samples. During that period, automated instrumentation based on HF furnaces and infrared (IR) detection systems that permitted simultaneous carbon and sulfur determination (i.e. from the same sample) developed rapidly. By the 1990s, the vast majority of
carbon and sulfur determinators utilized HF induction furnaces coupled to IR detection systems. Thermal evolution methods for oxygen, nitrogen, and hydrogen became prevalent in the 1930s. The vacuum fusion method was typically employed. This method uses a graphite crucible heated in a HF induction furnace to melt the sample under a vacuum. Furnace temperatures of about 1600°C were reported. The evolved gases were measured either volumetrically or gravimetrically. Oxygen could be determined using hydrogen reduction methods as well. Hydrogen could also be determined by hot extraction heating a sample to around 600°C in a vacuum. Around 1970, inert gas fusion instruments were designed to provide both improved sensitivity and reduced analysis time. The inert gas fusion technique of today features a direct current electrode (impulse) furnace that heats a graphite crucible resistively to temperatures approaching 3000°C in an inert carrier gas such as helium or argon. The sample is fused in the graphite crucible and the carrier gas sweeps the evolved carbon monoxide (CO), nitrogen (N₂), and hydrogen (H₂) to the detectors. If the carrier stream is split, oxygen and nitrogen can be determined simultaneously by thermal conductivity (TC) detectors. Oxygen can also be determined by IR detection as either CO or CO₂. Hydrogen is detected in a separate determinator using a TC detector. Since TC detectors are not selective, any gas other than the analyte or the carrier must be separated or removed to allow for accurate determination. Since 1980, simultaneous oxygen and nitrogen determinators have been using IR detection for oxygen and TC detection for nitrogen. Oxygen from the sample combines with carbon from the crucible to form CO. For additional sensitivity, the CO is usually converted to CO₂ via catalytic oxidation. CO or CO₂ is subsequently detected by IR. Modern hydrogen determinators employ resistance, HF induction, or electrode furnaces coupled to TC detectors for the determination of hydrogen by inert gas fusion or hot extraction.

### 3 CARBON AND SULFUR DETERMINATION

#### 3.1 Description of Methodology and Instrumentation

The carbon and sulfur contents of iron and steel products are routinely determined simultaneously using computer-controlled instrumentation based on the high-temperature combustion–IR detection method. Resistance-heated furnace units with temperature ramping features have been successfully used in determining surface carbon on steel products. However, resistance furnaces are of limited use for bulk (total) carbon and sulfur determinations in the myriad of steel and iron samples which require rapid and accurate determinations. Because of this shortcoming, the resistance-heated furnace has largely been replaced by the HF induction furnace. HF furnaces easily combust a variety of sample shapes and forms such as pins, slugs, chunks, chips, drillings, or powders. Figure 1 illustrates the combustion zone of a typical HF induction furnace. A HF induction furnace heats the sample by subjecting it to oscillating electric and magnetic fields. These fields heat electrically conductive samples by inducing electron motion. The combustion gas is carried out in a flow of pure oxygen to solid state IR detectors for accurate determination of the carbon as carbon dioxide (CO₂) and sulfur content as sulfur dioxide (SO₂).

A TC detector can also be used to measure carbon and sulfur. However, TC detectors are universal detectors (i.e. they respond to any gas that has a different TC from the carrier or reference gas), that rely on the separation or removal of gases other than the carrier gas and the gas being measured. Thus, analysis time and the potential for measurement interference are increased. For this reason, the majority of carbon and sulfur combustion instrumentation designed for the analysis of iron and steel does not utilize TC detector technology.

In contrast, IR detectors are designed to measure only the specific molecule of interest, making them the preferred detectors for this instrumentation. A typical IR detection cell consists of a cell body with a measure chamber, an IR source, a chopper motor with blades, a narrow bandpass (wavelength) filter, a
condensing cone, a solid state IR energy detector, and a preamplifier (Figure 2). The IR source, located at one end of the measure chamber, radiates visible energy as well as wavelengths in the IR spectrum. This energy is transmitted through the windows of a sealed measure chamber to the opposite end of the cell body. A chopper motor with blades rotates through the light beam, which presents the IR energy to the detector in pulses. CO$_2$ and SO$_2$ absorb IR energy at specific wavelengths within the IR spectrum, 4.27 µm and 7.37 µm, respectively. The pulsed IR energy passes through a wavelength filter selected for either CO$_2$ or SO$_2$; therefore, only the wavelength of interest passes on to the condenser cone that concentrates the energy at the detector. The detector is typically a pyroelectric device that responds to chopped or pulsed light and is AC coupled to a preamplifier.

At the beginning of an analysis, a starting reference level or “baseline” is established with only the oxygen (IR inactive) carrier gas flowing through the cells. During the combustion of the sample, the concentration of CO$_2$ or SO$_2$ increases in the gas stream and upon reaching the respective IR cell, IR energy is absorbed. This absorption of IR energy results in a decrease in voltage (signal) transmitted by the detector to the preamplifier, which is proportional to the CO$_2$ or SO$_2$ concentration in the gas stream. The Lambert–Beer law describes this process. Once the analyte has passed through the cell, the signal returns to its starting level. The integration of the CO$_2$ or SO$_2$ signal is directly correlated to the carbon or sulfur concentration in the sample. Figure 3 depicts the signal obtained from the analysis of a low alloy steel. Note that the signal is inverted for simpler interpretation. The length of the measure chamber (distance between the IR source and detector) has a direct effect on the sensitivity and range of the IR cell. The amount of IR radiation absorbed by the analyte is directly proportional to IR cell pathlength. Longer IR cell pathlengths are more sensitive and provide excellent low-level detection but limit detection at higher concentrations (detector saturates). The opposite is true for shorter pathlength IR cells. The typical measure chamber of a CO$_2$ IR cell is approximately 2–15 cm in length. SO$_2$ IR cell measure chambers are approximately 33 cm long, since the molar absorptivity of SO$_2$ is only a fraction of the molar absorptivity of CO$_2$. The flow rate of the gas through the IR cell is closely monitored and controlled. Separate carbon-only and sulfur-only combustion instruments, based on the same concept as a simultaneous carbon and sulfur instrument, are also manufactured for laboratory use.

3.1.1 Analysis Sequence

Figure 4 illustrates a typical flow diagram for a high-temperature combustion carbon and sulfur instrument. A preweighed sample of approximately 1 g is placed in a single-use high-purity ceramic crucible, and approximately 1 g of an appropriate metal accelerator is added. The crucible is placed on a ceramic pedestal. The pedestal is raised, the crucible is positioned in the center of the HF furnace work coil and sealed from the atmosphere. Purified oxygen is used to purge the combustion area. Power supplied to the induction coil establishes an alternating electric and magnetic field around the sample and accelerator. This combination rapidly heats the sample and accelerator causing them to combust. The carbon in the sample oxidizes primarily to CO₂, with some CO possibly produced depending on the sample type and carbon level. The sulfur in the sample is oxidized to SO₂. These gases are swept along with the oxygen carrier gas through a dust filter and drying agent into a solid state IR detector where sulfur is measured as SO₂. The gases are then passed through a platinized silica catalyst heated to 350°C which converts any CO to CO₂ and most of the SO₂ to sulfur trioxide (SO₃). The gases are then routed through a cellulose filter where the SO₃ is removed, while the CO₂ passes through the filter and is measured by a separate IR detector. The results are displayed as weight percent carbon and sulfur. Analysis times of one minute or less are typical.

3.2 Detection Limits and Ranges

State-of-the-art high-temperature combustion carbon and sulfur instrumentation is capable of determining total carbon and sulfur in iron and steel products from parts per million (ppm) to weight percent levels. A typical instrument will be able to analyze 1 g samples with carbon contents from 0.0001–3.5% and sulfur contents from 0.0001–0.4%. The ranges can be expanded upward by reducing the sample weight (i.e. the absolute amount of carbon or sulfur is less, but the percentage remains the same). In addition, a variety of instruments are optimized for either low or high levels of carbon and sulfur depending on the user’s needs. The detection limit (DL) is typically calculated from standard deviations of a number of consecutive measurements obtained on an individual instrument at or near the lowest measurable concentration of the element being determined. Instrument manufacturers may combine standard deviations from several individual instruments to determine DLs. One

Figure 4 Flow diagram for combustion carbon and sulfur determinator.
way of accomplishing this is to dose known quantities of CO₂ and SO₂ gases directly into the measure stream of an instrument. Some manufacturers offer carbon and sulfur instruments with built-in gas dosing capabilities. This feature allows for evaluation of the instrument’s ability to measure carbon and sulfur apart from the influence of variables such as sample homogeneity, combustion characteristics, and the contributions of the crucibles and accelerators. Mixtures of CO₂ and SO₂ in a carrier gas such as nitrogen (stable and IR transparent), dosed at various volumes, can be used to verify an instrument’s performance, linearity, and measurement range.

### 3.3 Analytical Procedures

In this section, analytical parameters that have an important impact on the precision of carbon and sulfur determinations are presented.

#### 3.3.1 Crucibles

The ceramic crucibles used to contain the sample and accelerator during the combustion cycle are a very important, yet often ignored, portion of the analytical technique. These crucibles, which are approximately 2.5 cm tall and 2.5 cm in diameter, are somewhat porous and can be contaminated during handling or storage. The crucibles typically weigh between 18 and 20 g each, while the nominal sample weight used is around 1 g. Therefore, just 1 ppm of carbon or sulfur impurity in or on the crucible will contribute 18–20 µg of carbon and/or sulfur to the analysis. This contamination translates to an 18–20 ppm contribution to the final result for a 1 g sample. The most problematic characteristic of crucible contamination is consistency; some crucibles may have more, some less, and some none at all. This inconsistency has a direct impact on analytical performance and is especially noticeable in ultra-low-carbon and sulfur grades of steel. In order to eliminate this variability, the crucibles should be preheated to volatilize the contaminants. Decontamination is typically accomplished by placing the crucibles in a tube or muffle furnace at 1350 °C for at least 15 min, or at 1000 °C for not less than 40 min. The crucibles are removed from the furnace, allowed to cool for approximately 2 min, and then placed in a desiccator before use. Once the crucibles have been removed from the furnace, they should only be handled with a clean pair of tongs. Table 1 contains a comparison of contaminated (unbaked) versus purified (baked) crucibles. It illustrates the impact that preheating the crucibles can have on the analytical result. The mean carbon result is decreased from 14.7 to 5.0 ppm by removing the crucible contaminants, while the sulfur results were reduced from 4.6 to 2.0 ppm. The baked crucible results demonstrate a three-fold improvement in low-level quantitation capabilities.

#### 3.3.2 Oxygen Supply

The purity of the oxygen that is used as both combustion and carrier gas can have an adverse effect on the analysis. Regular grades of oxygen may contain several parts per million of hydrocarbons such as methane (CH₄). A significant portion of these hydrocarbon gases will convert to CO₂ and H₂O during the combustion of a sample and bias the carbon results. Higher purity grades of oxygen can be used, although the cost may be significantly higher. Another option is to pass the incoming oxygen over copper oxide (CuO) heated to 600 °C to convert the hydrocarbon gases to CO₂ and H₂O. Then chemical reaction or adsorption with the appropriate reagents removes the CO₂ and H₂O. Some commercially available instruments have built-in heated catalyst furnaces designed to remove hydrocarbons from the incoming oxygen supply, but high-purity gases should be used to obtain peak performance from the instrument whenever possible.

#### 3.3.3 Accelerators

Steel and iron will combust in oxygen if elevated to a sufficient temperature. In order to assure rapid and complete combustion using a HF induction furnace, an accelerator is typically employed. An accelerator is an igniter and a flux, which promotes both combustion and a fluid melt by effectively lowering the melting point of the sample. Several high-purity metals have been used as accelerators in HF induction furnaces over the years; however, only a few are routinely used. Like the crucible, any analyte contained in the accelerator will contribute to
the result. To compensate properly for this contribution, the analyte should be present in the accelerator at only the lowest of levels and be uniformly distributed throughout the material. Metals such as copper, iron, tungsten, and tin have all been used successfully either by themselves or in combination with other accelerators. These accelerators are in chip or granular form, normally in the −10 to +40 mesh size.

Copper accelerator is typically used when carbon-only determination is required, as it may cause sulfur recovery problems in iron-based alloys. Iron is normally used with tungsten and/or tin when nonferrous samples are analyzed. Tungsten only is used when plain carbon steels are analyzed, but caution must be used to assure that complete recovery is obtained when analyzing high-alloy steels. Tin is used in conjunction with tungsten and is the accelerator of choice for simultaneous carbon and sulfur determination in steel and iron. This combination will result in the best overall combustion and recovery for the widest variety of steel and iron alloys. Approximately 1–1.5 g of accelerator is used with a 1 g sample of steel.

In order to obtain the most accurate results, the carbon and sulfur content of the accelerator is compensated for by the blank subtraction feature of the instrument. Typically, the accelerator is placed in a preheated crucible and a 1.000 g weight is entered into the weight stack of the instrument. The accelerator is burned and the carbon and sulfur contents are recorded. This process is repeated a minimum of three times and the average result for carbon and sulfur is entered as a blank. Another method to determine the blank starts by calibrating the instrument with a steel standard at a concentration where the contribution of the blank is insignificant. Then 1.000 g of a low-carbon and sulfur steel standard along with the accelerator is analyzed a minimum of three times. The difference between the average total carbon and sulfur measured and the certified carbon and sulfur content of the standard is considered the blank. The advantage of this procedure is that it simulates the combustion of the unknown samples more closely. It achieves this by producing similar temperatures and penetration of the sample into the crucible rather than simply combusting the accelerator itself. Thus, a more representative blank is recorded. The disadvantage of this technique is that the variability of the standard is transferred to the precision that can be obtained on the blank.

### 3.3.4 Methodology
The methodology can also adversely affect the precision of carbon and sulfur determinations. The performance of a method can be determined by conducting an interlaboratory study (ILS). Method development organizations such as the American Society for Testing and Materials (ASTM) and the International Organization for Standardization (ISO) produce written procedures and use an ILS to determine the suitability and scope of a method. The ILS will establish longer-term sources of variability within and between laboratories and instruments. For example, ASTM method E 1019 “Determination of Carbon, Sulfur, Nitrogen and Oxygen in Steel and in Iron, Nickel, and Cobalt Alloys” is a document that includes carbon and sulfur data obtained using an ILS to determine the scope of the combustion method.

### 3.4 Calibration
The accuracy of the combustion carbon and sulfur determination is dependent on proper calibration. Calibration is accomplished by analyzing reference materials with known carbon and sulfur contents. A major advantage of the combustion method for carbon and sulfur determination in steel and iron is that there are typically no matrix interference problems. Iron, cast iron, plain carbon steels, low-alloy steels, high-alloy steels, stainless steels, tool steels, specialty steels, and high-temperature alloys can all be analyzed using the same technique. Commercially available instrumentation is normally factory linearized (linear detector output from DL to saturation), which allows for single point calibrations. Typically, three to five replicates of a reference material are analyzed and the calibration slope is adjusted via the instrument’s software program. The reference materials used to calibrate are normally “consensus standards”, which means that the known or certified values are calculated from data obtained from various laboratories. Therefore, the accuracy of the standard is dependent on the accuracy of the method or methods used to determine these values. If several reference materials are analyzed on an individual instrument and the carbon and/or sulfur results do not agree with the accepted concentrations, either the instrument linearity or the accepted value of the reference is in question. Analyzing fractional weights of pure compounds such as calcium carbonate (CaCO$_3$) and barium sulfate (BaSO$_4$) can verify instrument linearity or, as mentioned in section 3.2, gas dosing may be used. A more practical approach incorporates two steel reference materials, one at the upper level of interest and one at the lower level of interest. For example, to verify the linearity of the carbon response of the instrument, steel reference samples with carbon contents of approximately 1.0% and 0.1% can be used. Each reference sample is analyzed several times using 1 g sample weights, with the proper accelerator, to determine an “expected value”. Then approximately 0.9 g of the 1.0% sample is mixed with approximately 0.1 g of the 0.1% sample. A new expected value is determined by multiplying the actual weight of
each sample by its expected value divided by the combined weight of both. The mixed sample is analyzed and the obtained value is compared with the expected value. The process is repeated with ca. 0.8 g of the high sample added to ca. 0.2 g of the lower sample and so on, until ca. 0.9 g of the low sample and ca. 0.1 g of the high sample are analyzed. The expected versus the obtained results are plotted to determine if the relationship is linear (Figure 5).

A linear relationship confirms the linearity of the instrument. Any reference sample employed in such a test must be homogeneous. The standard deviation of replicate analyses can be used to confirm homogeneity. Statistically, a minimum of five replicates of each level should be analyzed. This technique is also applicable to sulfur determination and it is a competent way to determine the linearity of a combustion carbon and sulfur instrument.

3.5 Sampling and Sample Preparation

Obtaining a suitable sample for analysis is very important. The sampling method must provide a sample that is representative of the material analyzed. Samples of liquid metal, cast products, wrought products, and other finished products are normally required. Samples may be in the form of solid slugs or pins, strips, chips, drillings, or powders. It is important that the sample to be analyzed is free of surface contamination. Solid samples, such as pins or slugs, can be abraded with a file, turned on a lathe, chemically etched, and/or washed in a suitable solvent such as acetone, and dried with warm air to remove surface contamination. Chips, drillings, and powders can be washed in acetone and dried with warm air. Care must be taken to assure that all traces of the solvent are removed. Surface contamination is an important factor for accurate analysis of low-carbon and sulfur grades of iron and steel. In some cases, surface carbon due to residual oils or lubricants can be removed by preheating the sample for 5–10 min at 420 °C in air. This procedure is typically applied to ultra-low carbon determination in high-purity iron and low-carbon steels. ASTM E 1806, “Sampling Steel and Iron for Determination of Chemical Composition”, and ISO 14284, “Steel and Iron – Sampling and Preparation of Samples for the Determination of Chemical Composition”, are two comprehensive reference documents that provide detailed sampling procedures for steel and iron.

3.6 Performance Data

Table 2 contains typical carbon and sulfur results obtained on a modern combustion instrument with IR detection. Carbon and sulfur determinators are typically employed in a quality control capacity by the iron and steel industries. In the USA, the Ford Motor Company introduced several quality control procedures and indices, which are widely accepted by both producers and manufacturers. These indices can be used to determine if the long-term performances of the iron and steel production processes are within their targeted requirements. One such index is the process capability ($C_p$) index, designed to compare

$\bar{x}$ = Mean, $s$ = estimate of standard deviation, RSD = relative standard deviation.
the reproducibility of the measuring process to the process specification limits. In effect, the process divides the acceptable specification range for the product by the process range (typically ±3 standard deviations of the measurements). \( C_p \) is, assuming a normal distribution, the proportion of the process range within the specification range. For example, Table 2 shows the average results of a white iron standard as 3.33% carbon, with a standard deviation of ±0.004%. If the lower specification limit and upper specification limit for the sample are 3.20% and 3.45%, respectively, calculating the \( C_p \) index yields the following:

\[
C_p = \frac{\text{upper spec. limit} - \text{lower spec. limit}}{6\sigma \text{ (process range)}}
\]

\[
C_p = \frac{3.45 - 3.20}{6(0.004)} = 10.42
\]

where \( \sigma \) represents the standard deviation of a population.

Nominal \( C_p \) values in the US manufacturing industries during the 1980s averaged approximately 0.67. There has been an upward trend in the minimum acceptable \( C_p \) index.\(^{(14)}\) Many companies are establishing targets of 2.0 or higher long term. When the \( C_p \) is applied to analytical instrumentation, sources of variation must be considered. These include quality of calibrants, homogeneity of material being analyzed, and the inherent reproducibility of the analytical method, including the detector. In order to measure the \( C_p \) of a carbon or sulfur detector alone, gas dosing may be employed. To measure the \( C_p \) of the method, well-characterized homogeneous reference samples, or pure compounds, may be employed. The \( C_p \) on production samples is defined by the deviations from the instrument, the method, and the sample. Descriptions of additional indices can be found in Bhote\(^{(16)}\) and Chambers et al.\(^{(17)}\) One procedure employed to characterize variation is gage repeatability and reproducibility analysis. This type of analysis can determine the proportion of measurement variability attributable to sample-to-sample variation, the instrument (reproducibility) and errors in the determination of the same sample by the same operator (repeatability). Further information concerning the use of gage reproducibility and repeatability (R&R) analysis is widely available.\(^{(18–22)}\)

4 OXYGEN AND NITROGEN DETERMINATION

4.1 Description of Methodology and Instrumentation

The oxygen and nitrogen contents of iron and steel products are routinely determined from the same sample using the inert gas fusion method. A typical inert gas fusion oxygen and nitrogen determinator is computer controlled and has two main components: an electrode furnace and a measurement unit. The electrode furnace is equipped with water-cooled alloy-tipped copper electrodes and is capable of heating a variety of high-purity graphite crucibles to temperatures up to 3000 °C in a flowing helium stream. The measurement unit contains the detectors along with the supporting hardware and software to perform the actual measurement. Figure 6 is

---

**Figure 6** Flow diagram for inert gas fusion oxygen/nitrogen determinator.
an illustration of a simplified flow diagram for a modern inert gas fusion oxygen and nitrogen determinator.

Oxygen is determined as either CO or CO$_2$ using IR detection, while nitrogen is determined using TC detection. CO and CO$_2$ absorb IR energy at specific wavelengths within the IR spectrum, 4.68 $\mu$m and 4.27 $\mu$m, respectively. The same type of IR cells are used in the inert gas fusion instruments as the combustion carbon and sulfur determinators. A description of a typical IR cell is found in section 3.1 of this article.

Nitrogen is determined as N$_2$ using a TC detector. A typical TC detection cell consists of one or two pairs of tungsten–rhenium wire filaments carefully matched in length. These filaments are mounted in a metal block maintained at a controlled temperature, usually in an oven. The filaments are connected in a Wheatstone bridge circuit that heats the filaments above the ambient temperature of the oven. One filament, or pair of filaments, is used as the reference side of the TC detector (carrier gas only). The other filament (or pair) is used as the measure side of the TC detector. The reference filament(s) are maintained at a constant gas concentration, temperature, and flow. The measure filament(s) are maintained at a constant temperature and flow, but the gas composition is allowed to vary. Helium is used as the carrier gas for a typical oxygen and nitrogen inert gas fusion determinator since its TC is significantly different from that of nitrogen. At the start of an analysis, helium is flowing through both the reference and measure sides of the TC detector resulting in a balanced output between the filaments. During the analysis of a sample, nitrogen as N$_2$ enters the measure side of the TC detector along with the helium carrier gas. The temperature of the measure filament(s) will increase because N$_2$ has a lower TC than helium. This temperature increase changes the resistance of the measure filament(s) causing an imbalance in the bridge circuit. This in turn is used to determine the N$_2$ content of the sample. Figure 7 is an illustration of a TC detection cell. Oxygen-only and nitrogen-only inert gas fusion instruments, based on the same concept as a simultaneous oxygen and nitrogen instrument, are also manufactured. If an oxygen-only inert gas fusion system uses an IR detector, then helium, argon, or nitrogen can be used as a carrier gas as these gases do not absorb IR radiation.

### 4.1.1 Analysis Sequence

A preweighed sample of approximately 1 g is placed in the electrode furnace sample loading port. The sample is retained in a chamber directly above the graphite crucible area. A high purity graphite crucible is placed on the lower electrode of the furnace and the furnace is closed. Figure 8 is a cross-sectional illustration of a typical electrode furnace. After a short purge cycle (to eliminate atmospheric gases), an electric current is passed through the crucible, which heats it to temperatures up to 3000 °C. Helium is flowing through the furnace, “sweeping out” contaminants that are released from the crucible. This heat cycle is typically referred to as the outgas cycle. After the outgas cycle, the furnace current is lowered which reduces the crucible temperature. An electronic baseline is established for each of the detectors, after which the sample is automatically dropped into the hot crucible. The sample is fused in the graphite crucible. The oxygen in the sample reacts with carbon from the crucible forming CO, while the nitrogen is released as N$_2$ and any hydrogen is released as H$_2$. These gases are swept along with the helium through particle filters and into a heated (400–600 °C) CuO catalyst furnace to convert any CO to CO$_2$ and H$_2$ to H$_2$O while the N$_2$ passes through unchanged. The gases are then routed to a CO$_2$ IR cell where the CO$_2$ is measured. H$_2$O absorbs IR radiation at a different wavelength (6.6 $\mu$m). Therefore, it does not interfere with the
CO₂ determination. The CO₂ and H₂O are removed by sodium hydroxide on a clay base and magnesium perchlorate, since they will interfere with the N₂ measurement. The helium flow carries the N₂ to the TC cell where it is measured. Oxygen and nitrogen are displayed as weight percent. A typical analysis cycle takes approximately 1 min. Some high-end instruments incorporate a feature that “ramps” the furnace temperature during the analysis cycle. The purpose of this technique is to separate forms of oxygen (oxides) and nitrogen (nitrides) in iron and steel. This feature is generally limited to research, since the separation of oxides and nitrides using this technique is somewhat complex and interpretation of the data requires detailed knowledge of the sample metallurgy.⁴²

### 4.2 Detection Limits and Ranges

State-of-the-art inert gas fusion oxygen and nitrogen instrumentation is capable of determining total oxygen and nitrogen in iron and steel products from parts per million to weight percent levels. These instruments are able to analyze 1 g samples of iron and steel with oxygen contents ranging from 0.000 05% to 0.1% and nitrogen contents from 0.000 05% to 0.5%. The ranges can be extended upward by reducing the sample weight. A variety of instruments are available that have expanded range capabilities. The DL of the instrumentation is normally calculated from standard deviations of a number of measurements on an individual instrument at or near the lowest concentration of the element being determined. Some instrument manufacturers may determine their published DLs and ranges (specifications) for a particular model of an instrument by combining statistics from a number of individual instruments. Dosing known volumes of N₂, CO, or CO₂ directly into the measure stream is another competent way to determine the measurement precision of an inert gas fusion oxygen and nitrogen determinator. This permits evaluation of the instrument’s detection system without the influence of other variables such as sample homogeneity and fusion characteristics. The instrument’s performance throughout its range can be evaluated by changing the volume and concentration of the dose gas. Mixtures of N₂, CO, or CO₂ in helium can be used as well. Some instrument manufacturers produce instruments with built-in gas dosing capabilities.

### 4.3 Analytical Procedures

In this section, analytical parameters that have an impact on the precision of the oxygen and nitrogen determination when using inert gas fusion instrumentation will be reviewed.

### 4.3.1 Crucibles

The graphite crucibles used to contain the sample during the fusion cycle are an important part of the analysis. They not only hold the sample during the fusion cycle, they are essentially carbon resistors that supply the heat that fuses a sample and the carbon that reacts with oxygen from the sample to form CO. These crucibles are machined from high-purity graphite rods and are made in a variety of shapes and sizes. The crucibles contain impurities including moisture and gases that have been absorbed during handling and storage. Just prior to transferring the sample to the crucible, these impurities are removed during the outgas cycle. State-of-the-art inert gas fusion oxygen and nitrogen instruments offer multiple outgas cycle capabilities that are operator selectable. Multiple outgas cycles subject the graphite crucible to several hot/cold cycles to enhance the removal of impurities from the crucible subsequently improving precision. The shape and size of the graphite crucible will have some effect on the application. Figure 9 shows some basic crucible designs used by inert gas fusion oxygen and nitrogen instruments. The standard crucible is designed for the majority of applications and typically can obtain a maximum temperature of 2600 °C. The high-temperature version is designed to reach temperatures of 3000 °C and is typically used for high-temperature alloys or refractory metals. During the fusion of a sample, electric current is flowing through the graphite crucible. As the sample melts, it will wet the inner walls of the crucible and change the resistance and temperature of the crucible. The standard and high-temperature versions are single wall crucibles. In some cases the sample may actually penetrate the crucible sidewall causing a loss in temperature. A third type of crucible used in these instruments is a double-wall design with both an inner and outer crucible. The inner crucible is replaced after each analysis, while the outer crucible is reused several times. This crucible offers improved temperature control and has a maximum temperature of 2200 °C. The current flows through the outer crucible and is not affected as the sample melts and penetrates in the inner crucible. This crucible is primarily used for oxide characterization.

![Graphite crucible designs](image-url)
With a 2200 °C maximum temperature, the double-wall crucible is not recommended for nitrogen determination owing to low nitrogen recovery.

4.3.2 Carrier Gas

The purity of the carrier gas is an important factor in obtaining suitable oxygen and nitrogen results on an inert gas fusion instrument. An ultra-pure carrier grade (UPC) of helium, with a minimum purity of 99.9995%, is typically required for this instrumentation. Trace amounts of H₂O, O₂, CO, or CO₂ in the helium carrier gas can cause some difficulties in this instrumentation. Most commercially available instruments will have reagent scrubbers such as sodium hydroxide on a clay base and magnesium perchlorate to remove CO₂ and H₂O, respectively, from the incoming gas supply. More advanced instruments will typically incorporate additional heated catalysts such as copper metal to remove O₂, and CuO to convert CO to CO₂, which is subsequently removed by the sodium hydroxide. During a normal analysis (as described in section 4.1), the sample is retained above the crucible until the outgas cycle is complete. The crucible temperature is lowered and electronic baselines for the detectors are established with the carrier gas flowing over the hot crucible. This allows the instrument to “mask” or subtract any contribution from impurities that are still in the carrier gas or the crucible. This mode of analysis is typically referred to as the automatic mode and it is the preferred mode of operation. In some instances, such as the analysis of powders or chips, the manual mode of operation is desirable. In the manual mode, the sample-loading chamber is bypassed. After the graphite crucible is outgassed and a short cool-down cycle has elapsed, the furnace is opened and the sample is loaded directly into the crucible. The furnace is closed and after a purge cycle the sample is fused. In this case, the electronic baselines for the detectors are taken from a cold crucible. Therefore, in the manual mode the instrument cannot “mask” the effects of impurities in the carrier gas. In addition, exposing the outgassed crucible to atmosphere causes higher and more erratic oxygen blanks.

4.3.3 Methodology

The methodology can also adversely affect the precision of oxygen and nitrogen. The performance of a method can be determined by conducting an ILS. Method development organizations such as the ASTM and the ISO produce written procedures and use an ILS to determine the suitability and scope of a method. The ILS will establish longer term sources of variability within and between laboratories and instruments. For example, ASTM method E 1019 “Determination of Carbon, Sulfur, Nitrogen and Oxygen in Steel and in Iron, Nickel, and Cobalt Alloys” includes oxygen and nitrogen data obtained using an ILS to determine the scope of the method.

4.4 Calibration

The accuracy of the inert gas fusion oxygen and nitrogen determinator depends on proper calibration. Calibration is accomplished by analyzing reference materials with known oxygen and nitrogen contents. A definite advantage of the inert gas fusion method for oxygen and nitrogen determination in iron and steel is the lack of matrix interference problems associated with this method. Samples of iron, cast iron, plain carbon steel, low- and high-alloy steel, tool steel, specialty steel, stainless steel, and high-temperature alloys can be analyzed using the same technique.

Commercially available instrumentation is normally factory linearized, permitting single point calibrations. Typically, three to five replicates of a reference material are analyzed and the calibration slope is adjusted using the software program of the instrument. The accuracy of the calibration is dependent on the accuracy of the method or methods used to determine the values of the reference. If several reference materials are analyzed on an individual instrument and the oxygen or nitrogen results do not agree with the accepted concentrations, either the instrument linearity or the accepted value of the reference is in question. Instrument linearity can be verified by analyzing fractional weights of a reference material or by combining reference materials in the same fashion as described in section 3.4 regarding carbon and sulfur calibration and linearity.

Combining reference materials is more important when linearizing the induction furnace combustion method than it is with the electrode furnace inert gas fusion method. The purpose is to maintain approximately 1 g sample mass while changing the analyte content. This is important because the sample mass couples with the induction field producing and maintaining sufficient temperatures to assure complete oxidation of the carbon and sulfur in the sample. In the case of the inert gas fusion method, the graphite crucible temperature is controlled by the current passed through it, not by the mass of the sample. Therefore, fractional weights of a single sample can also be used to verify instrument linearity for the inert gas fusion method. The main problem with mixing reference materials while linearizing using the inert gas fusion method relates to oxygen determination. As with carbon and sulfur, there are a variety of iron and steel reference materials in chip or granular form with certified nitrogen values. This facilitates the mixing of materials to simulate differing concentrations of nitrogen. There are virtually
no chip or granular iron or steel reference materials with certified oxygen values. This is primarily due to surface area and oxidation potential. Surface oxygen must be removed or otherwise accounted for in order to obtain accurate and precise oxygen results on iron and steel samples. Chip and granular samples have varying surface areas which correspond to varying levels of oxygen. While removing surface oxidation from solid samples is feasible, removing surface oxidation from chips and/or granular samples is not practical.

4.5 Sampling and Sample Preparation
Samples will need to be taken from liquid metal, cast metal, wrought metal, and finished products. The sampling method must provide a representative sample. For nitrogen determination, the samples can be in the form of solid slugs, pins, wires, strips, chunks, drillings, shavings, or powders. For oxygen determination, the samples should be solids with a shape that permits the surface to be mechanically prepared to remove surface oxygen. Surface oxidation is a primary consideration when accurate oxygen results are required. Two documents that contain comprehensive sampling guidelines for iron and steel are ASTM E 1806(13) and ISO 14284. Sample preparation of iron and steel for nitrogen determination can be as simple as washing in a solvent such as acetone and drying with warm air. Sample preparation for oxygen typically requires removing a portion of the surface to remove surface oxides, followed by washing in acetone and drying with warm air. If simultaneous nitrogen and oxygen determination is desired, the sample surface should be removed either by turning on a lathe or by abrading with a flat mill file, then washing in acetone and drying with warm air. Table 3 shows oxygen and nitrogen data obtained on a modern inert gas fusion instrument for a steel wire sample that was analyzed as received and after the surface was prepared by abrading with a flat mill file and washing in acetone.

4.6 Performance Data
Table 4 shows oxygen and nitrogen data obtained on a variety of iron and steel samples using a modern inert gas fusion instrument. Process capability or gage R&R procedures are commonly used for measuring the R&R of a process. For a more detailed explanation, refer to section 3.6.

5 HYDROGEN DETERMINATION

5.1 Description of Methodology and Instrumentation
The hydrogen content of iron and steel is routinely determined by fusing or heating a sample in an inert carrier gas followed by measurement with a TC cell. There are two main methods typically used for hydrogen determination: high temperature inert gas fusion and hot extraction below the melting point (which is usually at a temperature of 1100°C in an inert carrier gas stream). Like oxygen and nitrogen inert gas fusion instruments, a typical inert gas fusion hydrogen determinator is computer controlled and has a water-cooled electrode furnace coupled to a measurement unit. The electrode furnace has alloy-tipped

\[ \bar{x} = \text{Mean}, s = \text{estimate of standard deviation.} \]
copper electrodes capable of heating a graphite crucible to temperatures of up to 3000 °C. The measurement unit contains a TC detection cell along with the necessary hardware and software to perform the measurement. Argon is used as a carrier gas instead of helium. Argon has a significantly lower TC than hydrogen, so that subsequently excellent detection capabilities are attained. Since these instruments use a TC detector, gases such as CO, CO₂, and N₂ released from the sample must be removed or separated from the hydrogen if accurate measurement is to take place. Removal of these gases is accomplished by a series of reagents designed to react with the CO and CO₂ and by a column to separate the N₂ (N₂ is retained on the column for a longer time) from the hydrogen.

Another instrument design incorporates an induction furnace (instead of an electrode furnace) coupled to a measurement unit. The induction furnace can be used to fuse iron and steel samples in a graphite crucible, or it can be used to heat samples below their melting points in a quartz crucible using the hot extraction technique. When using an induction furnace, nitrogen is used as the carrier gas because argon will couple with the induction field and form a discharge. However, there can be a problem associated with using a graphite crucible and a nitrogen carrier gas: lower hydrogen recoveries are usually obtained. This reduced recovery efficiency is likely to be due to a reaction between the carbon from the crucible, the hydrogen from the sample, and the nitrogen carrier gas at elevated temperatures. However, the use of an induction furnace permits larger samples to be analyzed. Sample weights of 5 g are typically analyzed on an induction furnace unit, compared with 1–2 g samples which can be analyzed on an electrode furnace unit. When using the hot extraction technique in a quartz crucible, the crucible can be used several times and it does not have to be outgassed, as is necessary with the graphite crucible. The majority of users of the induction furnace hydrogen determinators use the hot extraction technique.

A third instrument design uses a resistance-heated furnace with a quartz reaction tube, nitrogen or argon as the carrier gas, and TC detector. The furnace is maintained at 1100 °C. This instrument does not use a crucible, but rather the samples are placed in the open end of the reaction tube and the tube tilts back sending the sample to a built-in stop in the hot zone of the furnace. The reaction tube is purged with an excess amount of carrier gas which creates a “gas blanket” at the open end of the tube. Thus, atmospheric gases are prevented from entering the tube. At the end of the extraction cycle, the tube tilts downward and the sample is expelled. This design offers simplicity and ease of operation as well as the ability to analyze 5 g samples. The instrument is not designed to analyze chips or granular samples.

Some models of resistance furnace instruments incorporate a piercing unit designed to determine “diffusible” hydrogen when used with an appropriate sampling device. The sampling device is a dual-chamber sample probe designed to take a sample from molten iron or steel and to trap the hydrogen that diffuses out of the sample during solidification. The sampler is placed in the piercing unit of the determinator, pierced, and then the diffusible hydrogen trapped in the outer chamber of the sampler is delivered to the TC detector for measurement. After this measurement, the sampler is removed from the piercing unit and the outer chamber is removed to expose the solidified sample. This solid sample is placed in the resistance furnace for extraction of the residual hydrogen. The diffusible and residual hydrogen results are combined and displayed as total hydrogen content.

5.1.1 Analysis Sequence

Figure 10 is a simplified flow diagram for an electrode furnace hydrogen determinator. An electrode furnace hydrogen determinator analysis procedure is similar to that of an inert gas fusion oxygen and nitrogen unit (section 4.1). A preweighed sample of 1–2 g is placed in the furnace loading port. The sample is retained in a chamber directly above the graphite crucible area. A graphite crucible containing approximately 1 g of high-purity tin flux (usually two 0.5 g tin pellets) is placed on the lower furnace electrode and the furnace is closed. Addition of tin prevents the fused sample from penetrating the crucible, resulting in more consistent results. After a short purge cycle, electric current is passed through the crucible heating it to temperatures near 2300 °C. Argon is flowing through the furnace to an exhaust port which removes contaminates released from the crucible and flux. This is typically referred to as the outgas cycle. Following the outgas cycle, the crucible temperature is lowered by reducing the electrical current and the argon is routed through the TC cell. An electronic baseline is established for the TC cell and then the sample is automatically dropped into the crucible. The oxygen in the sample reacts with the carbon from the crucible forming CO, the nitrogen is released as N₂, and the hydrogen is released as H₂. These gases are carried along with the argon through particle filters to Schutze™ reagent (iodine pentoxide over silica gel) which converts CO to CO₂ without oxidizing the H₂ to H₂O. The gases are then passed through sodium hydroxide on clay followed by anhydrite to remove the CO₂. The remaining H₂ and N₂ are carried along with the argon to a molecular sieve column that separates the two. The H₂ elutes from the column first and is measured by the TC cell. The N₂ exits the column approximately 1 min after
the H₂ has been measured, passing through the TC cell without being recorded. Hydrogen results are displayed as weight parts per million. A typical analysis cycle takes approximately 3 min.

A hydrogen determinator equipped with an induction furnace (Figure 11) can be used either to fuse a sample in a graphite crucible or to heat a sample to just below its melting point using a hot-extraction technique. The analysis sequence used for the fusion of a sample in a graphite crucible is similar to that of an electrode furnace. A preweighed sample of approximately 5 g is placed in a sample loading head and a single-use graphite crucible containing approximately 2 g of tin flux (usually four 0.5 g tin pellets) is placed on the furnace pedestal. The crucible is closed and the pedestal positions the graphite crucible in the center of the HF coil. After a short purge cycle, power is applied to the HF coil and the graphite crucible is heated by induction to a temperature of up to 1800°C. The nitrogen carrier gas sweeps out contaminants released from the crucible and the tin flux. Following the outgas cycle, the furnace power is shut off, the crucible is raised close to the sample loading port, and the sample is transferred to the crucible. The crucible is positioned in the center of the HF coil and power is applied. The crucible heats up rapidly, and the sample melts. Any hydrogen in the sample is released as H₂, the oxygen reacts with the carbon from the graphite crucible to form CO, while nitrogen is released as N₂. The CO is removed by passing through Schutze™ reagent converting it to CO₂, which is then removed with sodium hydroxide on a clay base. The nitrogen carrier gas carries the H₂ to the TC cell for measurement. Since nitrogen is used as the carrier gas, any nitrogen released from the sample has no effect on the measurement. Analysis time is approximately 4–5 min.

When used in the hot-extraction mode, an induction furnace hydrogen determinator analysis sequence is relatively simple. A preweighed sample of approximately 5 g is placed in a quartz crucible. The crucible, with the sample, is positioned on the furnace pedestal. The furnace is closed and the pedestal positions the crucible and sample in the center of the HF coil. After a purge...
cycle, power is applied to the HF coil and the sample begins to heat up by coupling with the HF current. The computer controls the furnace power and the sample heats up to approximately 1100°C. The hydrogen is released as H₂ and is carried to the TC detector by the nitrogen carrier gas. Oxygen and nitrogen are not released at this temperature. There is no outgas cycle and the sample loading port is not used. The analysis time is approximately 4–5 min. This is similar to a fusion analysis with an outgas cycle because it takes longer to extract the hydrogen when the sample is not melted. The extraction time is dependent on the cross-section and the weight of a sample.

A resistance-furnace-based hydrogen determinator (Figure 12) typically uses the hot-extraction method. A sample of approximately 5 g is placed in the open end of the reaction tube. The reaction tube tilts back and the sample slides to the center of the hot zone of the furnace, which is set at 1100°C. Hydrogen is released and delivered to the TC detector by the carrier gas. The analysis time is 4–6 min.

Some commercially available resistance-furnace hydrogen determinators are equipped with a piercing device used in conjunction with special probe samplers. These probes are used to sample molten metal and are designed to capture diffusible hydrogen. The diffusible hydrogen is measured when the probe is inserted in the piercing unit. Then the probe is removed from the piercing unit and the outer chamber of the probe is removed exposing the solidified metal sample. The sample is subsequently placed in the furnace for the determination of residual hydrogen. The diffusible and residual hydrogen values are combined and then reported as total hydrogen. The combined analysis time for diffusible and residual hydrogen determination is 5–8 min.

5.2 Detection Limits and Ranges

Modern hydrogen determinators have analytical ranges from 0.01–400 ppm of hydrogen based on 1–5 g sample weights. This range is more than adequate, as the hydrogen content of iron and steel typically ranges from 0.1–20 ppm. The DLs of a hydrogen determinator are usually calculated from standard deviations of a number of measurements obtained on an individual instrument at or near the lowest concentration of hydrogen being determined. Some instrument manufacturers may determine their published DLs and ranges for a particular model by combining statistics from a number
of individual instruments. Dosing known volumes of H₂ directly into the measure stream is an excellent way to determine the measurement capabilities of a hydrogen determinator. This evaluates the measurement capabilities of the instrument’s detection system without the influence of variables inherent in sampling, sample preparation, or actual analysis of a sample. Instrument performance throughout its range can be evaluated by changing the volume and concentration of the dose gas. Mixtures of H₂ in either nitrogen or argon can be used depending on the carrier gas of the instrument. Most manufactured hydrogen determinators have a built-in gas dose capability.

5.3 Analytical Procedures

Analytical parameters that have an impact on the precision and accuracy of hydrogen determination of iron and steel when using these instruments will be discussed in the following section.

5.3.1 Crucibles

Graphite crucibles are used when samples are fused in an electrode furnace and an induction furnace model in the fusion mode. They are an important component in obtaining optimum accuracy and precision. These crucibles are machined from high-purity graphite rods and may be further purified by vacuum degassing. Even so, they can contain hydrogen in the form of moisture from subsequent handling and storage. This contamination must be removed by outgassing the crucible just prior to transferring the sample to the crucible for analysis. Electrode furnace units typically have the capability to perform multiple outgas cycles. Multiple outgas cycles subject the graphite crucible to two or more hot/cold cycles which enhance the removal of impurities from the crucible. Induction furnace units usually do not offer this option because the crucible is evenly heated by the induction coil, which in turn removes the crucible contamination very effectively. The crucible temperature for hydrogen determination is typically lower than that used for oxygen and nitrogen determination. Temperatures of less than 2200 °C are normally used on an electrode furnace unit, depending on the crucible shape. A typical induction furnace unit will obtain temperatures less than 1800 °C during a fusion cycle. The quartz crucibles that are used during the hot-extraction technique on an induction furnace unit do not need to be degassed prior to use. However, they must be clean and should only be handled with tongs.
5.3.2 Flux

High-purity tin is used as a flux in the graphite crucibles. The tin is outgassed along with the crucible and trace contamination is not normally a problem. The tin dust that is generated due to volatilization during the outgas and analysis cycles must be removed periodically, otherwise problems with precision may occur.

5.3.3 Carrier Gas

The purity of the carrier gas used in these instruments is a critical component in obtaining accurate and precise hydrogen results. Typically, UPC grades with a minimum purity of 99.999% of argon and nitrogen are required. Moisture in the carrier gas and/or in the gas delivery lines is the main concern. All of the hydrogen determinators described in this section normally have incoming gas purification catalysts and reagents designed to remove small amounts of O₂, CO, and H₂O. However, sometimes trace amounts of H₂O and O₂ may make it through these reagents. Additional scrubbers, typically using lithium-based reagents, can be added further to remove trace amounts of H₂O and O₂.

5.4 Calibration

The accuracy of hydrogen determination using this method depends on proper calibration. There are few iron and steel reference materials with certified hydrogen values; therefore, gas dosing with hydrogen is the primary technique used to calibrate these instruments. The majority of manufactured instruments will have built-in gas dosing capabilities. Some instruments have multiple volumes, while others have a single volume with the capability to fill and dose several times during a single analysis to simulate various levels of hydrogen. Instrument linearity is normally not an issue with these determinators, because the hydrogen levels in iron and steel are generally less than 10 ppm.

5.5 Sampling and Sample Preparation

Sampling and sample preparation of iron and steel for hydrogen determination is extremely important. Hydrogen is mobile in iron and steel products and will diffuse out at room temperature. This diffusion can be very pronounced especially in samples with thin cross-sections. Hydrogen can be picked up by molten steel during production only to diffuse out after casting.\(^{(27)}\) This can lead to problems such as bleeding ingots, blowholes, embrittlement, and low ductility. Hydrogen is typically removed from liquid steel by vacuum degassing. In solid steel, hydrogen can cause internal ruptures.\(^{(28)}\) This tendency for hydrogen to diffuse out of steel makes sampling and sample preparation a definite challenge. Lowering the temperature of the sample reduces the diffusion of hydrogen from iron and steel. Samples taken from molten steel and iron must be quenched in ice water within 10 s after taking the sample. After the sample is cooled, it must be stored in a refrigerant such as liquefied nitrogen or a mixture of acetone and solid carbon dioxide. Likewise, samples taken from solid steel products should be kept cool at all stages of sampling, storage, and sample preparation. Filing, light grinding, or grit blasting can be used to prepare the surface of the test portion. The sample must be cooled at frequent intervals to minimize hydrogen diffusion. The test portion must be degreased by immersion in acetone, dried with a rough vacuum, and followed by immediate analysis. Evacuated sampling probes designed to capture diffusible hydrogen are available. These sampling devices are designed to take samples from molten metal and are used in conjunction with instruments equipped to handle them. When the probe is immersed in the melt, a fusible cap melts and liquid metal is pulled into an inner chamber. The probe is removed from the melt and seals as the metal solidifies.\(^{(14)}\) The probe is quenched in cold water and delivered to the laboratory for analysis. ASTM E 1806\(^{(13)}\) and ISO 14284\(^{(14)}\) contain sampling and sample preparation recommendations for steel and iron and are excellent reference documents.

5.6 Performance Data

Table 5 contains hydrogen results typically obtained from the analysis of stainless steel on the electrode furnace, induction furnace, and resistance furnace hydrogen determinators. A comparison of the hot-extraction technique versus the fusion technique of hydrogen analysis on an induction furnace appears in Table 6. For a review of process capability or gage R&R procedures that are commonly used for measuring the R&R of a process, refer to section 3.6.

X-ray Fluorescence Spectrometry in the Iron and Steel Industry

Didier Bonvin
ARL Applied Research Laboratories, Ecublens, Switzerland

1 INTRODUCTION

WDXRF spectrometry is well established as an analytical technique in the iron and steel industry. WDXRF is routinely used for the analysis of raw materials, sinters, slags and coupled with optical emission spectrometry (OES) for determination of the elemental composition of cast iron and steels (Figure 1).

One of the great advantages of WDXRF is its ability to analyze both conducting and nonconducting solids and liquids, whereas OES is used mainly for the analysis of metals. Both techniques are really complementary in the iron and steel industry:

- Elements such as boron, carbon and nitrogen at levels down to parts per million (ppm) cannot be measured by X-ray fluorescence (XRF) spectrometry but OES allows the quick reporting of their composition in metals, which is essential in this industry.
- All other elements required (except hydrogen) can be measured both by XRF and OES. The latter technique is superior at low concentration levels and WDXRF allows better precision at high concentration levels, e.g. nickel and chromium in high-alloy steels, leading to substantial gains in the amount of expensive alloying elements that are added to make a given alloy grade.
- Analysis of nonconductive materials, such as slags and sinters, is done very effectively and quickly by WDXRF.

For the analysis of metals, this complementarity means that very often the same specimen is used for both analysis techniques.

The demands for lower limits of detection, improved reliability of trace element analysis and tight control of alloy compositions have been steadily increasing in recent years. In addition, there is a trend within the iron and steel industry to place the analytical capability closer to the process that uses the analysis values so as to facilitate and speed up any corrective actions during production. These demands have led manufacturers of WDXRF instrumentation to design instruments that are more sensitive, have greater flexibility and which can be easily incorporated into automated laboratories. In this industry, energy-dispersive X-ray fluorescence (EDXRF) spectrometry is generally not selected because of its poor...
resolution and low performance with light elements (Na to Cl and particularly Mg, Al, Si and S) and its insufficient precision for major element analyses.

2 SAMPLING

It is well known that the analytical result is only as good as the sample submitted for analysis. All too often the taking of a representative sample is neglected while at the same time emphasis is placed on producing the most accurate analytical result using the most sensitive procedure or instrumentation. The effort put into achieving high-quality results is, of course, totally misplaced if an equivalent effort is not applied to sampling.

In the iron and steel industry, the samples submitted to the laboratory are intended to be representative of a shipload of iron ore, a stockpile of raw materials, intermediate and final products from the steel plant. This represents an enormous reduction in size to derive a laboratory-size sample of about 5 kg from many thousands of tons of original material. It is important that a sampling procedure is implemented which will

Figure 1 Processes in the iron and steel industry with various demands on analysis.
minimize the errors associated with sampling these large
volumes of material. If possible, samples should be taken
from moving streams using automatic cutters that remove
samples from the conveyor belt in a controlled and regular
manner.

The volume of material collected at the belt must be
reduced in a systematic way so that the sample that
ultimately reaches the laboratory is homogeneous and
fully representative of the original sample.

Tests have shown that a totally automated system that
takes and prepares the sample is capable of a precision
that is typically twice as good as that of a manual
system. The results of an automatic sampling system are
compared with a manual system in Table 1.1 Included in
the comparison is the analytical precision obtainable by
preparing and analyzing 10 replicate fusion beads. The
results emphasize the point that sampling is the limiting
factor in the achievement of precise analytical data when
analyzing large sample volumes.

The quality of sampling being of the utmost importance
with a view to obtaining representative results, Interna-
tional Standardization Organization (ISO) norms have
been produced, e.g. ISO 3081, 3082 and 3083 for sampling
and sample preparation of iron ores and ISO 14284 for
sampling and preparation of steel and iron.

For processed final products such as cast iron and
steel, a dip sample is usually taken from the molten

mass. An appropriate sampling device is used and the molten material is cast into a mold that provides rapid solidification (see Metal Analysis, Sampling and Sample Preparation in). The aim of the exercise is to produce a homogeneous and representative sample through a methodology which will ensure as high a reproducibility as possible and promote the formation of a fine-grained metallographic structure of the specimen. For these reasons, the mold casting has nowadays been largely replaced by immersion probes, which allow better control and reproducibility of the conditions in which the samples are taken. The most popular type of immersion probes produce the so-called lollipop, in either oval or disk form, as shown in Figure 2(a–c). They produce samples which will fit into the sample holders of all modern WDXRF spectrometers (maximum diameter 52–60 mm) and which present a flat surface of at least 30 mm diameter as the aperture of the holder for presentation of the sample to the WDXRF spectrometer is typically 28–30 mm in diameter.

3 SPECIMEN PREPARATION

Specimen preparation involves the procedure for preparing the sample in a form that is acceptable for introduction into the XRF spectrometer. It is clear that here again a high reproducibility of the preparation method is essential in order finally to ensure high precision and accuracy of the analyses. As seen above, a minimum flat diameter of 30 mm is generally desired for the analysis.

3.1 Metals

Metal samples include pig irons, cast irons, carbon steels, stainless steels and tool steels. Samples taken at the production point are usually of the correct size and consequently only require surface preparation. Only in the presence of visible defects such as air bubbles, nonmetallic inclusions or cracks will the operator have to take a decision about the validity of the sample.

The surface preparation procedures generally involve the use of abrasive paper either on a rotary grinder or on a belt finisher. Polishing striations give rise to a shielding effect, which results in a decrease in fluorescence intensities, especially for lighter elements, depending on the orientation of the sample. As expected, the decrease in intensity is more important when the XRF analytical devices view the sample perpendicularly to the striations than when they look at the sample parallel to them. For this reason, modern spectrometers are equipped with spinning of the sample holders to smooth out the influence of sample orientation, resulting in reproducible intensities on samples and standards.

Surface preparation is often started with a coarse alumina paper, e.g. 30–80 grit. The final surface finish is obtained by using finer grits, e.g. 120–180 grit, but this additional fine grinding is not practised everywhere. Grinding with alumina paper will, of course, contaminate the surface of the specimen with aluminum. Therefore, accurate aluminum content is generally determined by the OES technique, for which the depth of analysis is larger. Alternatively, silicon carbide abrasive paper can be used, but this will give a similar problem with silicon. Other types of abrasive paper such as zirconium oxide have been shown always to contain some alumina and therefore cannot solve the problem entirely. An interesting alternative is being applied in France on stainless steels where lathe preparation is used, which produces a good quality of surface without contamination.

3.2 Pressed Powders

Pressed powders offer the quickest and simplest form of sample preparation for WDXRF analysis. There are, however, limitations to the procedure and as long as these are recognized the method can be used for the preparation of most of the oxides and ferroalloys associated with the iron and steel industry.

The most serious disadvantages of the pressed powder procedure are particle size effects and mineralogical effects. Particle size effects are most significant in the determination of light elements where long-wavelength XRF radiation is emitted from the upper layers of the specimen and is influenced by differences in particle size. To minimize these effects, the particle size for pressed powders should be <50 µm. This is achievable with vibro-rotatory milling equipment. Care should be taken in the choice of mill vessel as contamination of the sample occurs during the milling process. In the iron and steel industry, vessels made of chrome steel are generally used because they are stronger and less expensive than the tungsten carbide (WC) versions. However, being less hard, they will wear quicker and also will contaminate the specimen with iron and chromium. This is why in cases where only minimum contamination can be tolerated WC should be chosen.

When the binding characteristics of the powder are not sufficient, a suitable binder/grinding aid must be added to the sample before milling the mixture. Generally a dilution of one part of binder to nine parts of sample is used. The powder can then be pressed into an aluminum cup or a steel ring.

One of the difficulties in carrying out an XRF calibration for pressed powders is that generally certified
reference materials (CRMs) cannot be used efficiently owing to mineralogical effects. The use of in-house standards of the same material types as those requiring analysis is recommended in order to produce calibration curves which will fit with the production samples.

3.3 Fused Beads

3.3.1 Introduction

Preparation of oxide materials as fused beads based on the original method of Fernand Claisse\(^2\) is the best method of obtaining accurate results. Essentially, the fusion procedure consists of heating a mixture of sample and flux at high temperature (800–1200 °C) with a borate so that the flux melts and dissolves the sample. The overall composition and cooling conditions must be such that the end product after cooling is a one-phase glass. Heating of the sample–flux mixture is usually done in platinum alloy crucibles (e.g. Pt–5% Au), but graphite may also be used when conditions permit. Both particle size effects and mineralogical effects are removed as the original structure of the sample is completely destroyed by the fusion at high temperature and the elements are then embedded in a truly homogeneous matrix. Thus improvement in reproducibility and accuracy can be achieved with this method compared with the pressed pellets method, as shown in Table 2.\(^1\)

3.3.2 Advantages of the Fusion Technique

The fusion technique also has additional advantages:

- Possibility of high or low specimen dilution: the dilution level is often dictated by the ability of the given oxide to be fused completely and without segregation. Lower dilution allows better limits of detection and decreases the preparation errors as a larger amount of sample is weighed.
- Possibility of adding compounds such as heavy absorbers or internal standards to decrease or compensate for matrix effects.
- Standards of desired composition can be prepared from pure oxide materials in order to generate calibration curves.
- CRMs can be used without restriction to generate calibration curves.
- Possibility of obtaining very large calibration ranges within the same calibration curve when the proper matrix corrections are used (Table 3).\(^3\)

Figure 3 shows an example of such a calibration curve for Ca covering a concentration range from 200 ppm to 94%.

3.3.3 Variables in the Method

There are still many decisions that need to be made in order to achieve accurate analyses with the fusion bead procedure.

3.3.3.1 Choice of Flux  
This is the most important aspect as the flux must be able to dissolve all the different material types that require analysis. Many preferences exist among the various laboratories engaged in major element analysis of oxide materials. The most frequently used fluxes are borates, namely lithium tetraborate, lithium metaborate and sodium tetraborate. Lithium tetraborate is widely used as it is suitable for many applications. Sometimes mixtures of these fluxes are more effective, e.g. fluxes with 12 parts of Li₂B₄O₇ to 22 parts of LiBO₂ (4) or 65% Li₂B₄O₇ – 35% LiBO₂ (5).

Nonwetting additives are often used in order to reduce the retention of the melt in the crucible during pouring, reduce any sticking of the bead to the mold and therefore allow cooling without risks of cracking. Additives can be liquids such as solutions of HBr, NH₄I or LiF or solids such as LiBr.

Oxidizing agents, e.g. LiNO₃ or NaNO₃, are added when some metallic particles occur in the sample in order to save the platinum ware and obtain a homogeneous bead.

Because of all these additions, accurate weighing is essential in order not to introduce serious errors.

3.3.3.2 Fusion Apparatus  
Types of fusion apparatus range from simple gas burners or muffle furnaces to sophisticated automatic fusion machines with multiple burners or induction coils.

3.3.4 Disadvantages of the Method
The disadvantages of the method are relatively obvious and constitute the reason why pressed powders are still used in many instances:

- time of preparation;
- cost per specimen due to the consumables, e.g. flux, additives and platinum ware;
- loss of volatile elements during the fusion;
- possible errors when weighing flux and sample.

4 CALIBRATION OF THE X-RAY FLUORESCENCE INSTRUMENT

4.1 Introduction
In order to obtain the concentrations of the various elements present in the sample, the XRF spectrometer must be calibrated. This is done by measuring reference materials, either a CRM or a secondary reference material (SRM).

Overlap corrections are necessary when a spectral line of an element interferes with the analyte line. The contribution from the interference line to the intensity of the analyte line must be corrected. Such a correction depends on the sensitivity of the instrument for the given analysis lines, and therefore they have to be determined experimentally, for example by running binary standards.

In addition, it is essential that matrix corrections be used in order to achieve the desired accuracy. The correction coefficients can be determined experimentally with a large number of reference materials. However, the common practice nowadays is to generate theoretical factors through specific software programs which take into account the conditions of excitation (anode type, kV, mA), the geometry of the instrument and the matrix considered. Finally, matrix correction must be applied to the intensities obtained on the XRF instrument through a multivariable regression program in order to obtain the corrected calibration curves.

4.2 Setting-up Samples and Control Samples
In order to maintain the calibration over time, a number of stable samples representing the high and low intensities (not the concentrations) found in the various calibration curves are chosen. They are called setting-up samples. The drift correction, also called recalibration or standardization, needs to be performed at given intervals. Modern high-power WDXRF instruments are very stable in the long term and standardization is often practised with intervals of 1 week or more. Procedures are now used in order to determine at which time the standardization must take place. On-line statistical process control (SPC) software performs the statistical analysis as a background task as soon as a stable control sample has been run. In case of nonstatistical behavior of a given analysis channel, an alarm appears on the instrument screen requesting a selective standardization. SPC allows guaranteeing of the precision and accuracy of the spectrometer, which is required by quality systems such as the ISO 9000 series of standards.

Small, low-power desktop XRF machines, in contrast, require a monitor sample (also called type standard) to be used generally before each analysis in order to correct for possible drift.

It is not necessary that the setting-up samples have the same matrix as the production samples, but it is essential that they are very stable and easy to clean. For example, for slags or sinters, flat, polished, glass–ceramic samples are very adequate whereas for calibration of iron or steel, diamond-polished metallic samples are selected. (6)

c Material Types and Analytical Requirements

In the iron and steel industry, analyses on materials and products are carried out for two very distinct purposes: control of the process and control of incoming material for invoicing purposes. Analysis requirements are generally expressed in terms of limits of detection, of precision at given concentration levels and of accuracy. In view of the high performance of modern WDXRF instruments, accuracy depends more on the quality and number of standard samples used for the calibration and on the matrix and overlap corrections than on the intrinsic qualities of the instrument. This is why instrument manufacturers nowadays utilize numerous CRMs and are able to deliver instruments that are fully factory calibrated.

The materials that are analyzed by WDXRF in the iron and steel industry are metallic (Table 4) or nonmetallic (Table 5). A third category can be defined for the various coatings and other miscellaneous materials (Table 6).

Two parameters allow rating of the importance of a given material within a plant, its frequency of analysis and the desired reporting time. The response time varies as a function of the distance that the specimen has to travel to reach the analytical equipment, the degree of automation involved and the type of XRF spectrometer (sequential, simultaneous or simultaneous/sequential).

5.1 Analysis of Iron Ores

Producing steel from natural material is achieved through reduction of iron ores in a blast furnace or a direct reduced iron (DRI) process as opposed to the alternative method using steel scraps fused in an electric furnace (Figure 1).

Two procedures are available for the preparation of iron ores in a suitable form to allow XRF analysis. The preparation through fusion into glass beads (section 3.3) opens up the possibility of having a standardized method and is described in ISO 9516.(7)

Pressed powder briquettes of iron ore are employed in cases where ultimate accuracy in not required, when the number of samples to be tested is large,(8) when trace elements must be determined or when an additional X-ray diffraction (XRD) analysis is intended on the same specimen.

The XRD technique permits the determination of the compounds or phases present in a sample. However, only limited use has been made of quantitative XRD in process control as such instruments are usually housed in the Central Research Laboratory, well away from the process.

The latest instrumentation incorporating an XRD device into a conventional WDXRF instrument permits...
the determination of both the elemental and phase composition of specimens.\(^9\) The determination of the relative proportions of hematite (Fe\(_2\)O\(_3\)) and magnetite (Fe\(_3\)O\(_4\)) in iron ore, for example, results in better utilization and optimization of the available mineral resources. This kind of instrument can replace the time-consuming wet chemical methods employed up to now to determine these different phases.

More details on the analysis of iron ores can be found in **Iron Ore, Sample Preparation and Analysis of**.

### 5.2 Analysis of Sinters

Sinters represent the majority of the ferrous products charged into the blast furnace (around 75% or more). They are made of iron ores, coke and limestone heated to 1200 °C and sintered by aspiration of air through the mixture. This allows substitution of the raw iron ores by a man-made material with desired specifications and keeps the fluctuations of the firing conditions in the furnace as small as possible.\(^10\)

The XRF technique only determines the presence and amount of elements. In the case of sinters and other oxidic materials, some elements are to be reported as oxides rather than elements, e.g. SiO\(_2\), Al\(_2\)O\(_3\). Hence the calibration of the XRF instrument for these elements is based on the oxide concentrations so as to obtain the desired oxidic reporting.

Determination of the oxides/elements (Table 7) is carried out by XRF after preparation either as pressed pellets\(^11\) or as fused beads in the same manner as for iron ores.

The pressed pellet method is also desired when using low-power desktop XRF equipment installed at the sinter plant, so as to have a quick and simple preparation. In such a case an analysis is performed every hour and a moving average over three samples is taken, leading to acceptable results.\(^12\)

One of the most important controls to be applied in sinter is the amount of FeO phase, which allows one to monitor the sintering process and to avoid problems in the blast furnace operation during oxide reduction. XRF does not allow a distinction between the various phases of iron oxide, i.e. Fe\(_2\)O\(_3\), Fe\(_3\)O\(_4\) and FeO; it only measures the total iron in the sample. Other methods are required for the FeO value, e.g. titration with potassium dichromate or XRD. A recent advance in instrumentation has been the integration of an XRD system into an XRF spectrometer, which allows both elemental and phase determination to be carried out on the same specimen.\(^9,13\) The determination of FeO in sinter is possible with good precision with such an integrated XRD system with a counting time of <100 s.

### 5.3 Analysis of Slags

Slags originate from various stages in the iron and steel process, e.g. blast furnace, converter, basic oxygen furnace (BOF) (also called BOS), electric arc furnace or ladle.

In the blast furnace, slag is formed from the impurities in the iron ores (known as the gangue), the flux and the coke ashes. It is a complex silicate of aluminum, calcium and magnesium containing small quantities of oxides of manganese and iron and calcium sulfide.\(^10\) Slag has a double role: it permits the removal of the gangue thanks to its fusibility and fluidity, and it allows reactions of exchange with the liquid metal and permits control of the process in order for the desirable elements to remain in the melt while the others are removed. As an example, in an electric arc furnace the slag formation process can be controlled by adding oxygen, carbon and slag formers to the melt. This will promote the formation of CO instead of MnO and FeO and help keep these elements in their metallic form in the melt. The basic slag formers such as lime (CaO) and magnesia (MgO) will help to neutralize the acidity of the slag in order to save the refractory bricks of the furnace.\(^14\)

Slag samples are crushed and ground in a mill to obtain a small enough particle size. Magnetic separation of metallic residues is done on the milled fractions before further preparation. The pressed powder method is generally used for routine elemental determinations in slags, especially when fast reporting is important (converter and ladle slags). High-speed slag analysis is gaining importance as a shorter reporting time allows, for example, optimization of the desulfurization of steel.\(^15\) However, when a certificate must be produced in order to sell the slags or if accuracy is more important than speed of response, the fusion bead method is used. The oxides of interest in the slags are shown in Table 8 with their

**Table 7** Typical elements or oxides determined in sinters, their concentration ranges and the typical reproducibility of analysis over 20 days using a high-power instrument with X-ray tube settings of 50 kV, 40 mA.\(^13\) (Copyright ASTM. Reprinted with permission.)

concentration ranges and typical precision and accuracy for pressed pellets.

Other elements oxides are determined in various types of slags as S up to 1.5%, V up to 5%, Ni up to 0.3%, K₂O up to 10%, Na₂O up to 5%, Cr₂O₅ up to 10%, Zn up to 0.1% and F up to 2%.

XRF calibration for slags is relatively straightforward with few interelement corrections to use, especially when a specific calibration is applied for each type of slag. With pressed powder preparation, SRMs originating from the process in question should be preferred. If slags are prepared as fused beads, CRMs and SRMs can be mixed and the same calibration can be used for iron ores, sinters and slags.

5.4 Analysis of Irons

Blast furnace iron, also called pig iron, is brought to the desulfurization station and then to the converter, where it is transformed into steel by oxidation of the excess carbon (Figure 1). At each of these stages samples are taken in order to control the quality of the product (Table 4).

Cast irons are iron–carbon base alloys containing various amounts of silicon, manganese, phosphorus, sulfur and trace elements. Wide variations in properties can be achieved by varying the balance between carbon and silicon, by alloying with various metallic or nonmetallic elements, and by varying casting and heat treatments.

Two types of cast irons are to be considered in order to achieve good precision and accuracy of analysis: white irons and gray irons. Gray cast irons present an inhomogeneous structure with flakes of carbon, which will impair the results especially on phosphorus and sulfur. Therefore, it is recommended to obtain molds and cooling conditions which will produce a white cast iron structure. In addition, all CRMs for cast irons are prepared by chill casting, which promotes the formation of a white iron structure with finely dispersed iron carbides. The sampling is often done with an immersion probe, which delivers a compact coin-like specimen (Figure 2c). Obtaining a slag-free specimen is very important as slag would lead to incorrect results for sulfur and silicon.

A proper surface can be achieved with a surface grinder (belt or disk) using an aluminum oxide abrasive paper. Although some referenced methods specify abrasive size up to 240 grit, in practice coarser papers (e.g. 60- or 120-grit) are often selected in a production environment owing to time constraints. Another very effective specimen preparation is by using a 37-grit alumina stone wheel on a horizontal grinder. The specimen is fixed magnetically. Coolant should be used at first when grinding off the casting crust. The final grinding is done without coolant. Fine polishing is only necessary when carbon is to be determined. Diamond polish surface preparation allows the best results in terms of accuracy, but it is time-consuming and seldom used in production control.

The main elements that are to be determined in irons are listed in Table 9. The ranges given correspond also to factory calibrations that XRF instrument manufacturers can typically propose.

* Nodular iron only.
Calibration of the XRF equipment will require basically the same overlap and matrix corrections as are used for steel analysis (section 5.5).

Some qualities of steel require sulfur contents below 10 ppm and impose the use of iron with very low sulfur concentrations, typically around 20–30 ppm. In that case, the WDXRF instrument must be especially accurate for low levels of sulfur. In addition, the analysis result is required within the shortest possible time, hence the use of simultaneous instruments fitted with fixed channels for the required elements.

The improved determination of carbon in cast iron by WDXRF has become possible as a result of several important developments. A superior light element analyzing crystal (synthetic multilayer structure) better excitation of light elements using thinner X-ray tube windows, higher excitation conditions and closer tube to sample coupling have all contributed to the detection limit of carbon in steels being lowered to 50 ppm (in a 100-s counting time) in the most sensitive instruments. Significant improvements in the detection limits (Tables 18 and 19), as well as in terms of precision (Table 10) for all the other elements normally determined in iron and steel, have also been achieved as a result of these instrumental enhancements. Concerning the determination of carbon and other ultralight elements by XRF, it is important to understand that their characteristic XRF radiations are of low energy and can emerge only from a very thin layer at the surface of the specimen (0.03 µm for carbon in an iron matrix). Hence reproducibility of surface preparation is of the utmost importance in order to achieve a successful analysis of ultralight elements by XRF.

### 5.5 Analysis of Steels

Examination of the output of large steel companies reveals that they can be producing up to 1500 different steel qualities. Preparation of a specific steel quality takes between 3 and 5 h from initial receipt of the hot metal to final production of the steel quality. During this time, samples are taken at regular intervals to monitor the progress of the process. All these samples require as quick a chemical analysis as possible owing to the short residence times of given charges at each treatment station. Hence reproducibility of surface preparation is of the utmost importance in order to achieve a successful analysis of ultralight elements by XRF.

Specimens from all the production stages are nowadays generally transported by a pneumatic tube system into the laboratory, where they are prepared and analyzed. To save costs and increase speed of response, full automation of the whole preparation and analysis is being implemented in many iron and steel plants. This is discussed in Automation of Analytical Control in the Steel and Metals Industry.

The analytical steps from sample preparation to transmission of the results must be performed as quickly as possible. Specimens undergo grinding, cleaning and punching prior to analysis. Not more than 180-grit abrasive paper should be used for grinding the specimen surface otherwise variations from operator to operator become too large. During steel making, the carbon level must be controlled and adjusted down to parts per million levels. Low-level carbon, nitrogen and sulfur are measured by combustion analyzers on 1-g slugs, which are punched from the metal after fine grinding (Figure 2a). Alternatively, carbon determination can also be done by OES when the precision and limit of detection (LOD) that can be achieved by XRF are not sufficient. For some or all of the other elements which enter into the composition of the steels (Table 11), both the OES and XRF analysis results are often taken into account. Sometimes an average of the two determinations is used for accuracy at the expense of speed of analysis, as the specimen must be reprepared after having been burned by the spark of the OES spectrometer.

WDXRF is used extensively for the analysis of the high-alloy steels because of the very good precision achieved on major elements (Figure 4a and b). In addition to the elements listed in Table 11, cerium, magnesium, selenium and tellurium are sometimes determined. The typical LODs for two types of XRF instruments can be found in Tables 18 and 19, and precisions at various concentration levels are given in Table 12.

The typical precisions (Table 12) required by the steel industry for elemental determinations can be achieved with counting times ranging from 20 s on

<sup>a</sup> Analysis done by OES for low levels of given element.
<sup>b</sup> Analysis done alternatively by combustion analyzer.

Concerning the calibration of the XRF instrument, overlap corrections are necessary notably for the following interfering element–analyte pairs: Mo–P, Cu–P, Mo–S, Ti–V, V–Cr, Cr–Mn, Fe–Co, Ni–Cu, Cu–Zn, W–Zn, Mo–Zn, W–As, W–Ta, Ni–Ta, Cu–Ta, Ni–W, and Sn–Pb. These corrections depend on the intrinsic sensitivity of the instrument to the given analytical line, therefore they are determined experimentally using binary standards. Note that iron being the matrix is not reported but is measured in order simultaneous instruments to 300 s on sequential machines (see Table 20).

Concerning the calibration of the XRF instrument, overlap corrections are necessary notably for the following interfering element–analyte pairs: Mo–P, Cu–P, Mo–S, Ti–V, V–Cr, Cr–Mn, Fe–Co, Ni–Cu, Cu–Zn, W–Zn, Mo–Zn, W–As, W–Ta, Ni–Ta, Cu–Ta, Ni–W, and Sn–Pb. These corrections depend on the intrinsic sensitivity of the instrument to the given analytical line, therefore they are determined experimentally using binary standards. Note that iron being the matrix is not reported but is measured in order simultaneous instruments to 300 s on sequential machines (see Table 20).

suppliers, there is a trend to diminish the number of analyses carried out on ferroalloys and to rely on the analysis certificates submitted by the suppliers.

There are a large variety of ferroalloys (Table 13) and their preparation for XRF analysis will vary depending on the hardness of the material and the demands in terms of analytical precision and accuracy.

5.6.1 Sample Preparation

Preparation of ferroalloys for analysis is not a simple task. Three main procedures can be employed.

5.6.1.1 Remelting with Pure Iron

This method allows a metal button to be obtained by remelting the ferroalloy mixed with pure iron chips in a high-frequency furnace. Casting is done through centrifugation of the melted metal. Crucibles of 20 mL are made of refractory material and molds of copper–beryllium are often used. The most important parameters to be controlled are the dilution ratio and the melting and casting times and temperatures. The best results are obtained with dilution ratios of sample to pure iron varying from 3 : 5 to 3 : 17 for the most difficult ones. Melting temperatures are chosen between 1300 and 1900°C with melting times of about 2 min. The disks obtained look like thick coins and are polished with abrasive paper in the same way as steel samples.

Using the remelting method, the grade element concentration of all the ferroalloys can be determined with tolerances of ±0.2 and ±0.4% (2σ) and the relative standard deviation (RSD) values for the minor elements are below 5%.

5.6.1.2 Pressed Pellets

Ferroalloys are usually extremely hard and difficult to crush or mill, but this method is rapid and inexpensive. The grinding time and grain size (40–70 µm) must be strictly reproduced for the best results. Various binders are used, e.g. 10% methylcellulose, before pressing at 20–40 tons.

RSDs of 0.1–0.15% around the calibration curve can be achieved for the major elements, and between 3 and 5% for minor elements.

As the specimen preparation is the same for all ferroalloys a single analytical program can be built incorporating all of them (Table 14). This is a very useful starting point before refining the program into specific

5.6.1 Sample Preparation

Preparation of ferroalloys for analysis is not a simple task. Three main procedures can be employed.

#### 5.6.1.1 Remelting with Pure Iron

This method allows a metal button to be obtained by remelting the ferroalloy mixed with pure iron chips in a high-frequency furnace. Casting is done through centrifugation of the melted metal. Crucibles of 20 mL are made of refractory material and molds of copper–beryllium are often used. The most important parameters to be controlled are the dilution ratio and the melting and casting times and temperatures. The best results are obtained with dilution ratios of sample to pure iron varying from 3 : 5 to 3 : 17 for the most difficult ones. Melting temperatures are chosen between 1300 and 1900°C with melting times of about 2 min. The disks obtained look like thick coins and are polished with abrasive paper in the same way as steel samples.

Using the remelting method, the grade element concentration of all the ferroalloys can be determined with tolerances of ±0.2 and ±0.4% (2σ) and the relative standard deviation (RSD) values for the minor elements are below 5%.

#### 5.6.1.2 Pressed Pellets

Ferroalloys are usually extremely hard and difficult to crush or mill, but this method is rapid and inexpensive. The grinding time and grain size (40–70 µm) must be strictly reproduced for the best results. Various binders are used, e.g. 10% methylcellulose, before pressing at 20–40 tons.

RSDs of 0.1–0.15% around the calibration curve can be achieved for the major elements, and between 3 and 5% for minor elements.

As the specimen preparation is the same for all ferroalloys a single analytical program can be built incorporating all of them (Table 14). This is a very useful starting point before refining the program into specific

calibration curves for each type of ferroalloy in the quest for the best results.

The use of specialized synthetic multilayer crystals and the enhanced sensitivity of modern WDXRF spectrometers allows much improved precisions and LODs to be achieved for elements, which used to be impossible in the past. A new element such as boron can now be determined in ferroboron prepared as pressed powder with good precision (Table 15).

5.6.1.3 Fusion Beads In order to fuse ferroalloys with a flux and cast the resultant melt into a mold, the ferroalloy must first be converted into an oxide. Oxidation of ferroalloys by simple heating is possible but the reaction is exothermic and if done directly in a platinum–gold crucible considerable damage to the crucible takes place. Various methods have been proposed using muffle furnace or fusion machines. In some cases Sr(NO3)2 is used as oxidant, in others NaNO3 with fluxes made of a mixture of Li2B4O7 and Na2CO3. A recipe for Fe–Mo preparation proposes a flux made of CaCO3, Na2CO3 and Na2B4O7, while a mixture of only CaCO3 and Na2B4O7 is used for Fe–V and Fe–Ti. Dilution can be as high as a 1 : 35 sample to flux ratio, thus diminishing the matrix effects but also the intensities obtained on the XRF instrument, which can lead to difficulties with trace elements.

A successful method28 protects the platinum crucible during oxidation of the ferroalloys by melting a known mass of lithium tetraborate (Li2B4O7) and coating the walls of the crucible by rotating it during cooling. The oxidation is completed by chemical reaction with lithium carbonate (Li2CO3) and finally the oxidized ferroalloy is dissolved in Li2B4O7 flux.

Using an appropriate fusion method, major elements present deviations around the calibration curve of about ±0.1% while RSDs for minor elements are better than 3%23.

Dissolution in acids followed by drying and then fusion of the residue with suitable fluxes into a glass disk has been used with success for main-element determinations on a limited number of ferroalloys. However, this procedure has the disadvantage of being time-consuming and labor intensive29.

5.7 Miscellaneous Analyses

5.7.1 Surface Analysis

For surface analysis of steel sheets, specimens 50 mm in diameter are punched out of the metal sheet. They are analyzed directly for determination of the levels of nonmetallic elements present on the surface, such as K+, Na+, Ca2+, P, S, Si and Cl−. These can reveal or explain production anomalies or breakdowns. Stains and product appearance also depend on these surface elements. With constant and fast monitoring, remedial action can be taken in good time. Such determinations can be systematic in some cases.

Total surface iron is determined on the metal after pickling, rolling, annealing or degreasing. The specimen is taken by application of an adhesive tape to the sheet. The tape is removed from the sheet and adhered to a cellulose membrane. Adherent iron is measured on the membrane. These tests are performed occasionally in case of problems.

5.7.2 Coating Analysis

Deposition (hot-dipped or electrogalvanic) of different elements on steel sheet has become a common practice
in order to achieve various properties, e.g. anticorrosion. The layers vary between, among others, Zn, Zn−Al, Zn−Ni, Zn−Fe, Sn, Cr and plastic, depending on the desired property.

XRF can be used to quantify the thickness or surface density of the layer deposited subject to certain conditions. As an example, Figure 6 shows the calibration curve obtained for a chromium layer deposited on a steel plate. Table 16 gives the corresponding numerical results. Other elements in the layer have also been measured. Surface densities down to 20 mg m$^{-2}$ can be measured.\(^{(31)}\)

Examples of analysis of other types of coating are shown in Table 17, where the determination of thickness and composition is reported; the term “Given” indicates the result obtained by gravimetric analysis (mass thickness) or by atomic absorption (concentration) and “Found” indicates the XRF result.\(^{(32)}\)

Plastic coatings of different colors are used on steel sheets. Their thickness ranges between 25 and 200µm and they contain inorganic elements that vary depending on the coating manufacturer and the date of delivery. Analysis by WDXRF provides evidence on claims about poor quality such as color changes or adhesion problems due to insufficient stabilizer or other necessary additives.\(^{(33)}\)

5.7.3 Other Analyses

Systematic analyses per incoming batch of materials and weekly analysis are carried out for other types of materials which are used in the iron and steel industry, e.g. bauxite, olivine, dolomite, limestone, calcium hydroxide, casting fluxes and mold powder. Specimens are prepared either as pressed powder or fused beads depending on the plant.

Coal ash and coke ash are analyzed for the determination of elements and oxides such as SiO$_2$, Al$_2$O$_3$, CaO, MgO, Fe, S and P.

Determination of the presence of toxic heavy metals is required in the dust from electro-filters.

### 6 CHOICE OF SPECTROMETER

Various types of WDXRF spectrometer are employed in the analysis of samples from the iron and steel industry. The correct type of instrument depends very much on the analytical requirements of the individual application, e.g. speed of analysis, number of elements and throughput required. It is worth reviewing the capabilities of these instrument types as they each have specific applications.

6.1 Sequential X-ray Fluorescence Spectrometer

Modern sequential XRF spectrometers, with improved tube to sample coupling, high-power generator (up to 4.2 kW) and X-ray tube fitted with a thin beryllium window (down to 50 µm), are capable of producing very high count rates from solid samples. Faster electronics allow linearity of counting on detectors up to $2 \times 10^6$ counts per second, making it possible to exploit the better sensitivity of these instruments.

This high sensitivity permits the use of short counting times. In some instances the required precision can be reached with counting times as short as 2 s. Hence it is possible for sequential spectrometers to be used in the determination of up to 12 elements in metal samples, slags or sinters in less than 2 min. The limitation of the sequential spectrometer appears as soon as the number of elements requiring determination increases. Typically low-alloy steels require up to 22 elements, for which complete analysis can only be achieved in about 5 min (see Table 20). This is inadequate when the ladle holding time is 3 min.

LODs close to 1 ppm in a 100-s counting time can be reached for many of the important elements. As can be seen in Table 18, the limits of detection for a 4-s counting time are five times higher, but for many of the elements are still acceptable for the requirements of the iron and steel industry. Evidently the counting time can be selected depending on the element and the performance required.

In the manufacture of specialty steels, the group of elements requiring determination can change as the demand for the product changes. Thanks to its universal goniometer, the sequential XRF spectrometer is capable of determining up to 84 elements of the periodic table (beryllium to uranium) provided that the appropriate crystals and collimators are fitted. This versatility makes it an ideal choice when the number of elements amounts to about a dozen. In addition, large-capacity sample changers can be fitted. Batches of up to 170 samples can then be analyzed automatically. Mixtures of pressed powder briquettes and glass fusion beads are possible with these large-capacity changers.

6.1.1 Standardless Analysis

Although X-ray instruments in the iron and steel industry are predominantly used for routine analysis of process control samples, there is often a need for flexibility to handle nonroutine samples submitted to the laboratory. For example, new sources of raw materials, coal, fluxes or environmental dust and specialty products may need to be characterized. Difficulties arise when these nonroutine samples do not fit into any of the calibrated programs. The development of the so-called “standardless” or semiquantitative analysis packages has met this requirement. Two types of semiquantitative programs have been developed. One employs a global scanning procedure followed by spectral processing while the other measures individual peaks and backgrounds at predetermined spectral positions followed by intensity processing. These packages require a universal goniometer, as fitted in a sequential instrument, and the necessary crystals, collimators and detectors to cover the elements of the periodic table from fluorine to uranium. They are generally calibrated at the XRF manufacturer’s plant using standards made as much as possible of a pure element or oxide and sophisticated spectral and matrix corrections.

With such a standardless analysis package, the spectrometer is ready for analysis of a wide range of material types and matrices upon delivery to site. Analysis of unknown samples can commence immediately. Loading of the prepared sample into the XRF spectrometer followed by activation of the program yields a comprehensive determination of all major, minor and trace elements present. Even shift operators with no XRF knowledge can obtain an analysis in 10–15 min. Although the accuracy and precision achieved with these programs are not as good as those obtained with quantitative programs calibrated with matching standards on limited ranges, their capabilities are improving as more efficient matrix correction algorithms, spectral line overlap and background correction models are developed.
### 6.2 Simultaneous X-ray Fluorescence Spectrometer

In a stainless-steel plant, the turnaround time is critical and analyses for up to 28 elements or more may be required. A high-power XRF spectrometer (up to 4 kW) fitted with fixed-element monochromators will do the job as the elements are measured simultaneously. Each monochromator is generally based on a curved crystal geometry where the XRF from one given element of the specimen is focused into the detector slit. The detector will be selected from a flow-proportional counter (FPC) for the lighter elements to a sealed detector with appropriate gas filling for the light and medium elements. A scintillation counter will be used for the analysis of the shorter wavelengths typical of the Kα or Kβ lines of heavier elements. For light elements, either a curved or a flat crystal geometry can be chosen. Typical counting times for elements in stainless steels are 30–40 s (Table 19), with loading and unloading of the sample taking 20 s, hence a turnaround time of 1 min is easily achievable.

The disadvantage of the simultaneous system lies in its inflexibility: no element other than those chosen as monochromators at the time of purchase of the equipment are possible and no backup exists in case of failure of a monochromator.

#### Table 19 Typical LODs (3σ) obtained on a modern simultaneous WDXRF instrument in a 30-s counting time on the monochromators (3.6 kW)

a ML, multi-layered synthetic microstructure pseudo-crystal.
b PET, pentaerythritol.

Sometimes low-power (200 W) simultaneous instruments are used exclusively for specific control of the oxides, e.g. iron ores, sinters and slags, when the response time is not critical. The disadvantage of these low-power systems is their inability to serve as backup of the OES equipment for the metals analysis.

### 6.3 Simultaneous/Sequential X-ray Fluorescence Spectrometer

The option to have fixed-element monochromators, which perform an analysis in parallel to a sequential device, is often of considerable benefit in the iron and steel industry. In general, these instruments have a high capacity of fixed channels, e.g. 28 or more, and are fitted with sequential devices, which can be scanners or goniometers. Scanners are limited in angular range and are fitted with only one or two crystals and a single detector. More than one scanner is always necessary to handle all the elements of the periodic table covered by the XRF technique and generally the elements below aluminum (Z = 13) are not included. In contrast, a true goniometer as used in sequential XRF instruments is universal. It can be fitted with several crystals and collimators and a minimum of two detectors in order to determine the elements of the periodic table from beryllium to uranium (with some restrictions for the ultralight elements). There are many advantages of having a simultaneous/sequential instrument fitted with a universal goniometer:

- the goniometer can be employed for the quantitative analysis of any elements that are not fitted as fixed monochromators;
- it can back up any of the fixed channels if needed;
- the goniometer can be employed for qualitative determination of any element through wavelength scanning;
- it can be used for “standardless analysis” of nonroutine samples (see section 6.1.1).

Table 20 presents the measurement time necessary to achieve the precision values listed in Table 12. Various configurations of instrument are considered:

- simultaneous, fitted only with fixed channels, a counting time of 40 s is used for all channels, fast instrument but without flexibility for any additional element;
- pure sequential, fitted with one universal goniometer, counting time is chosen depending on the element, flexible but slow;
- simultaneous/sequential system with one goniometer and 14 fixed channels, almost as fast as a simultaneous spectrometer and has the flexibility of adding extra elements whenever required.
Table 20  Measurement times (s) required to obtain the precision levels (2σ) generally needed in the iron and steel industry with various configurations of instruments

The complementarity between fixed monochromators and a universal goniometer in a simultaneous/sequential instrument is demonstrated: fixed channels are chosen for the elements requiring long counting times while the goniometer is used for the easier elements.

6.4 Simultaneous/Sequential X-ray Fluorescence Spectrometer with X-ray Diffraction Capability

Given the increasing demand for process integration and total characterization of materials, a wavelength-dispersive spectrometer has been developed which effectively combines WDXRF and XRD within the same instrument. Employing the same pressed powder briquette as prepared for XRF analysis, the integrated XRD system is capable of the quantitative analysis of specific phases or minerals present in the sample. The performance of the XRF monochromators and goniometers being in no way degraded by the addition of the XRD capability, such an instrument can bring some advantages for process control in the iron and steel industry, notably for the determination of iron phases in iron ores and of FeO in sinters and monitoring of the reduction in the DRI process.

6.4.1 The X-ray Fluorescence/X-ray Diffraction System for Direct Reduced Iron Production

New and improved processes for the conversion of iron ore to metallic iron involve direct reduction where iron ore is reduced to iron without going through the pig iron stage. The iron oxide can be in the form of ore, concentrate or pellet and the reduction process uses either gas or coal as the reducing agent. The advantages of this process are low levels of impurities and chemical and physical consistency.

Close monitoring of the progress in the reduction of Fe₂O₃ (hematite) to Fe is important. The determination of the metallic component in the reduced material is possible by wet chemical procedures, but is time-consuming, needing at least 30 min for the analysis of one phase, and therefore cannot be classified as a process control analysis. Because hematite has a distinctive XRD peak, it is possible to monitor the progress of this conversion by observing the decrease in the iron oxide (hematite) concentration in the material. Therefore, the quantitative determination of the hematite content of the ore passing through the system can be achieved using the integrated XRF/XRD instrument.

7 CONCLUSION

As we enter the 21st century, there are various trends in the iron and steel industry as concerns the XRF technique:

- Routine analyses are increasingly carried out by nonexperts. In addition, scientists wish to focus on the details of the chemistry rather than on the particularity of the measurement technique. Therefore, instruments must become more and more autonomous and include the required analytical expertise.
- The WDXRF technique is being used for more varied applications, which call for innovative methods and standardless analysis programs.
- There is a need for more complete information about the sample, e.g. elemental and phase information, which will promote instruments combining different analytical techniques.
- There is a trend to decentralize the measurements and to bring the analytical equipment closer to the process. This means very often that the instruments...
are to be fully automated with connection to automatic sample preparation and located in protected cabins.

Surfaces: Introduction

G.E. McGuire
MCNC, Research Triangle Park, USA

When selecting a technique to characterize a material, one of the key factors to be considered is the region and volume of material to be analyzed. When the surface is selected for analysis, it presents some of the most challenging aspects of analytical chemistry. Compared to other types of analysis, the volume of material analyzed is extremely small. When the depth of analysis is only a few ångstroms deep and the spatial resolution is on the order of 500 Å, the number of atoms available for analysis may be below 1000. Impurity atoms that may be present in the parts per million or parts per billion level in this region typically fall below the detection limits of most surface analytical techniques. This is precisely the situation that one faces in trying to analyze the dopant concentration in the junction region of an advanced semiconductor device, for example. There is a tendency to want to increase the current density of the probe beam to enhance the signal-to-noise; however, this may lead to specimen damage in the region of analysis. This may be a result of localized heating, beam-stimulated desorption, bond breaking and chemical decomposition. In spite of these potential problems, surface analysis is accomplished routinely in many applications. There is an ongoing challenge to improve the sensitivity and spatial resolution of the techniques.

When is surface analysis important? It is widely recognized that surfaces are important in many technical areas. Surface reactions are involved in catalytic reactions; friction and wear are influenced by molecular interactions at surfaces; interfaces influence the electrical properties of semiconductor devices; and interfaces control the interactions between biological systems and man-made implants. Many other examples could be given, since the list of situations where surfaces play an important role is quite long. The range of materials that require surface analysis is quite broad, including metals, glasses, organics, biomaterials, semiconductors, etc. A wide diversity of surface analysis techniques have been developed, which that are capable of analyzing the many different types of materials and provide the range of information that is sought regarding the composition, microstructure and physical properties of specimens. These techniques are often complementary, such that two or more of them may be used in order to gain a thorough understanding of a surface.

The analysis techniques can be grouped in many different ways; however, one convenient way of examining them for comparison is the type of information they provide. For example, several of the techniques reviewed in the Surface Analysis section provide images of the surface. A scanning probe is one of the principal methods of generating spatially resolved images. Techniques that utilize scanned probes are discussed in the article Scanning Probe Microscopy, Industrial Applications of. Surface microstructure is important in understanding many of the interactions that occur at surfaces. One of the most broadly used surface imaging techniques is the scanning electron microscope (SEM), which generates surface images from secondary electrons produced by high-energy primary electron beam bombardment. This technique has been available for more than forty years and is discussed in the article Scanning Electron Microscopy in Analysis of Surfaces. However, steady improvement in the spatial resolution of SEMs has resulted in instruments that image areas of less than 15 Å. The versatility of the sample chamber and stage allows the analysis of specimens up to 300 mm in diameter. In comparison, scanning probe techniques (discussed in the article Proximal Probe Techniques), such as scanning tunneling microscopy (STM) reviewed in the article Scanning Tunneling Microscopy/Spectroscopy in Analysis of Surfaces, atomic force microscopy (AFM), and others, achieve atomic resolution but generally over a small field of view, on the order of hundreds of ångstroms. As a result, detailed information is revealed about surfaces that has heretofore not been available. This has increased our understanding of surfaces and surface interactions at a pace that was not anticipated just a few years ago. The additional information available from the scanning probes has opened up many new areas of research. The early efforts in STM and AFM were directed toward understanding the techniques and improving the instrumentation. The emphasis has now shifted toward application, as is illustrated in the articles Scanning Tunneling Microscopy, In Situ, Electrochemical in the section Electroanalytical Methods and Atomic Force Microscopy in Analysis of Polymers in the section Polymers and Rubbers. However, more traditional techniques such as SEM are just as popular as ever and are used in a wide diversity of fields, such as forensics, which is discussed in the article Scanning Electron Microscopy in Forensic Science in the section about Forensic Science. In one sense, the scanning probe techniques have become the instruments of choice for research. They provide detailed information on the surface, but a well-controlled surface is required. Many of the studies utilizing scanning probe techniques are conducted in vacuum or controlled ambient. Atomic level control is not necessary for many technologies where the surface plays an important role. For these surfaces the more versatile SEM may be a more appropriate characterization tool.
Information beyond the initial surface is essential for many investigations. The near surface and interfaces play an important role in many technologies. One method of probing beyond the outer surface is to utilize high-energy electron beams that penetrate through a specimen. The image is captured on photographic film or an electronic imaging device such as a charge-coupled device (CCD) camera. The high-energy primary beam may be scanned (optional) as in the SEM. Images of specimens up to several thousand ångstroms thick may be obtained with a spatial resolution below 2 Å. This is discussed in the article **Electron Microscopy and Scanning Microanalysis**. The high-energy probe is the basis for other complementary techniques such as electron energy loss spectroscopy (EELS). As the electrons pass through the specimen they lose discrete amounts of energy through the excitation of electrons of the atoms along their path. The energy loss can be measured using an electron energy analyzer, and can be used as a means to identify what elements are present. It is also possible to do EELS from the front surface of a specimen, using reflected low-energy electrons. This approach is discussed in the article **Electron Energy Loss Spectroscopy in Analysis of Surfaces**.

Chemical composition is another important aspect of surfaces that must be characterized. Energetic beams, such as electrons, ions and X-rays, are used to probe the surface. By exciting secondary radiation or particles, or by examining the energy lost during the excitation of the specimen, one can determine the elemental composition. Techniques such as Auger electron spectroscopy (AES) or X-ray photoelectron spectroscopy (XPS) use energetic electrons and X-rays, respectively, to excite secondary electrons. The Auger and photoelectron have characteristic energies which are utilized for elemental identification, while the signal intensity is an indication of the concentration. What distinguishes AES and XPS from other analytical techniques that rely upon high-energy electrons or X-rays for analysis is that the mean free path of the secondary electrons is very short, providing a surface analysis of the top few monolayers of material. The article **X-ray Photoelectron and Auger Electron Spectroscopy** in the section X-ray Photoelectron Spectroscopy and Auger Electron Spectroscopy reviews the fundamentals of these techniques, while the articles **X-ray Photoelectron Spectroscopy in Analysis of Surfaces** and **Auger Electron Spectroscopy in Analysis of Surfaces** review some of their applications. Applications that utilize the enhanced energy resolution when soft X-rays from a synchrotron are used for excitation are discussed in the article **Soft X-ray Photoelectron Spectroscopy in Analysis of Surfaces**. Likewise, surface analysis utilizing ion beams, such as in secondary ion mass spectrometry (SIMS) or ion scattering spectroscopy (ISS), relies on the limited path length of scattered ions or the secondary ions produced by energetic ion bombardment. The secondary or scattered ions provide elemental analysis of the surface. The sensitivity of the various techniques varies by several orders of magnitude and is usually best for the ion sputtering techniques such as SIMS, which has a sensitivity down to the parts per million level or less in most specimens. The application of SIMS is discussed in the article **Secondary Ion Mass Spectrometry as Related to Surface Analysis** in the section about **Mass Spectrometry**, while the application of ISS is discussed in **Ion Scattering Spectroscopy in Analysis of Surfaces**.

There are many other physical properties of surfaces that must be characterized. Optical techniques are a class of analysis techniques that provide some of this information. For example, optical techniques provide information on the thickness, composition and band gap of materials, information that is generally not available by other analysis techniques. For example, ellipsometry is utilized by the semiconductor industry to determine the thickness and separation of dielectric layers such as oxides and nitrides even when present in multiple layers. This can be accomplished in a nondestructive fashion, which makes it attractive for research as well as production applications. Film thicknesses as small as a few monolayers can be determined. This is discussed in the article **Ellipsometry in Analysis of Surfaces and Thin Films**. Differences in the optical properties of surfaces, such as in differential reflectance spectroscopy, reviewed in the article **Differential Reflectance Spectroscopy in Analysis of Surfaces**, can highlight subtle differences in surfaces, even though information on the exact compositional difference is not provided. In addition, optical techniques such as photoluminescence (PL) can be utilized to measure impurity concentrations down to the parts per trillion level, and defect concentrations in monocrystalline materials at depths of up to one micrometer. PL is reviewed in the article **Photoluminescence in Analysis of Surfaces and Interfaces**. Optical techniques also probe the chemical bonds formed at surfaces. This is accomplished using infrared and Raman spectroscopy which are discussed in the articles **Infrared and Raman Spectroscopy in Analysis of Surfaces** and **Infrared and Raman Spectroscopy and Imaging in Coatings Analysis**.

There are over one hundred surface analysis techniques. Some of the most widely utilized surface analysis techniques are described in this section. The most popular ones are more general in nature and can be utilized on a wide range of materials and specimens. All of the surface analysis techniques have a special niche for which they are best utilized.

1 Introduction

AES is an extremely useful analysis technique used to identify and quantify the elements present on solid surfaces. The AES sampling depth is on the order of 0.5 to 2 nm, while the detection limits are approximately 0.25 atomic percent. All elements except hydrogen and helium can be detected, and in many cases, information on the chemical bonding can be extracted from AES data.

AES probes the electron energy level of ions in a solid undergoing auto-ionization and is a subset of a broader field called secondary electron spectroscopy. The initial ions may be produced by X-ray irradiation or most commonly by a primary electron beam of energy $E_p$ in the range of 1–10 keV. The electrons emitted or backscattered from the surface are analyzed as a function of their kinetic energy $E$, and the resulting electron energy distribution $N(E)$, or its first derivative, $dN(E)/dE$, is referred to as the spectrum.

Auger electrons, which are a component of the secondary electron spectrum, were first discovered by Pierre Auger in 1925. The initial suggestion that these electrons could be used for analytical purposes was made in 1953 by Lander. It was not until 1968 that Harris demonstrated the utility of the technique. The period between 1967 and 1969 was marked by a rapid evolution of electron energy analysis instrumentation, first by Weber and Peria and later by Palmberg. Palmberg also introduced the idea of combining AES and inert ion etching to obtain compositional depth profiles. Finally, in 1970, MacDonald used a focused electron beam rastered across the surface to obtain two-dimensional compositional analysis of the surface. This gave rise to a subset of AES known as scanning Auger microscopy (SAM). Although improvements in hardware and data analysis tools have been introduced over the intervening years, the basic

Auger electron spectroscopy (AES) is an electron energy spectroscopy which probes the electronic energy levels of atoms, using electron or X-ray beam stimulation. Irradiation of a sample with one of these stimuli causes electron emissions which can be energy analyzed to obtain an energy distribution. Since the energies of the Auger electrons are characteristic of the atomic core and/or valence level energies, they contain chemical information about their source atoms. As a result, the recorded energy spectra can be analyzed to determine the atomic composition (atomic percent) of the sample, and, in some cases, extract chemical bonding information. Further, since the escape depth of Auger electrons is limited to the first few monolayers of the sample, the technique has a high surface sensitivity. When used in conjunction with an ion source, AES can provide compositional information as a function of depth (depth profiling). Although AES was initially used primarily for fundamental surface science applications, the technique has developed into an important analytical tool for a broad range of surface and materials science applications, including surface reaction studies, surface segregation studies, and thin film growth studies.
AES and SAM analysis tools used today were developed in the span of a few years between 1967 and 1970.

The remainder of this article is designed to provide a basic understanding of AES, the equipment required to implement the technique, and the type of information it can provide. Section 2 discusses the fundamentals of the Auger process. Section 3 describes the instrumental methods used to obtain AES spectra. Section 4 reviews the interpretation of AES data. Section 5 provides an overview of several of the major applications of AES.

2 FUNDAMENTALS

AES involves ionization of atomic core levels, the subsequent relaxation of the excited atom by the emission of a so-called Auger electron (auto-ionization), and the escape of the Auger electron into the vacuum (where the electron's kinetic energy is measured by an electron spectrometer). Either an incident photon or an electron beam may stimulate the initial ionization process. Thus, Auger electrons are commonly encountered in X-ray photoelectron spectroscopy (XPS). For this discussion, however, we will focus primarily on electron beam induced Auger electron emission.

When a primary electron beam of energy $E_p$, typically in the range of 1 to 10 keV, irradiates a solid surface, it produces secondary and backscattered electrons with an energy distribution $N(E)$. A typical $N(E)$ versus $E$ plot or spectrum for these secondary electrons is shown in Figure 1. This spectrum is comprised of four distinct energy regimes. The peak at $E = E_p$ is due to the elastically backscattered primary electrons. These electrons may be used for low-energy electron diffraction (LEED) for sufficiently low primary energies and for reflection high-energy electron diffraction (RHEED) for sufficiently high primary energies.

Features in the energy range $E_p - 50 \text{ eV} \leq E \leq E_p$ (or plasmon loss region) are associated with primary electrons which are inelastically scattered by plasmons. These electrons are studied in plasmon loss spectroscopy (PLS), electron energy-loss spectroscopy (EELS), and high-resolution electron energy-loss spectroscopy (HREELS).

At the opposite end of the spectrum in the energy range 0 eV $\leq E \leq 50$ eV, the rapidly rising background is due to "true" secondary electrons. This feature is associated with electrons that have lost nearly all of their energy through inelastic collisions, and its intensity and cut-off energy are very sensitive to small changes in the work function.

Peaks in the energy range $30 \text{ eV} \leq E \leq E_p - 50$ eV include those due to Auger electrons, plasmon loss features associated with the Auger electrons, ionization loss electrons (due to the initial ionization event), and diffraction features. It is the Auger electrons in this region to which attention is now directed.

2.1 Auger Emission

Figure 2 illustrates the basic physics of the Auger emission process. The atomic levels shown here are identified using both standard spectroscopic and X-ray notation. As discussed by Briggs and Riviere, it is the latter that is used most commonly in identifying Auger spectra. When a sample is irradiated by a primary electron beam having energy $E_p$, electronic levels with ionization potentials less than $E_p$ may be ionized. In the case illustrated here, this is the K level (or $n = 1$ level). The excited atom quickly relaxes as an electron from a higher level ($L_1$ or $n = 2$ level in this case) fills the core hole. This may be accompanied by either the emission of a characteristic X-ray having an energy $E_K - E_{L_1}$ or by the radiationless emission of a second electron ($L_2$ in this case) having a kinetic energy $E_K - E_{L_1} - E_{L_2}$. The notation $L_2$ is used to indicate that this is not the energy of the $L_2$ level in the ground-state atom, but rather, it is the energy of the $L_2$ level in the excited atom having a hole in the $L_1$ level.

The relaxation process involving X-ray emission is called X-ray fluorescence (XRF), while using X-ray notation is called Auger emission. These are competitive processes whose relative probabilities are illustrated in Figure 3 for an initial core hole in the K level. Similar considerations are true for all other initial core hole possibilities (L, M, N, etc.). The Auger electron emitted in the situation depicted in Figure 2 is identified as the KL$_1$L$_2$ Auger transition. Other possible Auger transitions
Figure 2: Schematic diagram showing the Auger emission process. In this figure the L$_2$ and L$_3$ levels are split. For situations where there is no splitting the combined level is referred to as L$_{2,3}$.

Figure 3: The probability of core hole relaxation by either XRF or Auger emission, plotted as a function of atomic number. (Reproduced with permission from D. Briggs, J.C. Riviere Practical Surface Analysis: Volume 1: Auger and X-ray Photoelectron Spectroscopy, eds. D. Briggs, M.P. Seah, © 1990 John Wiley & Sons Limited.)

Involving the illustrated levels include KL$_1$L$_1$, KL$_1$L$_3$, KL$_2$L$_2$, KL$_2$L$_3$, KL$_3$L$_3$.

It has been noted that it is not possible for H or He to emit Auger electrons. Clearly, this is because the Auger process involves at least two different states and two electrons in states higher than the initial core hole. Likewise an isolated Li atom cannot emit an Auger electron, but Li in the solid state may do this by taking advantage of additional electrons in the valence level.

Following the empirical method developed by Chung and Jenkins,$^{(9)}$ the kinetic energy of the Auger transition ABC from an atom with atomic number $Z$ is given by Equation (1)

$$E_{ABC}(Z) = E_A(Z) - rac{1}{2}[E_B(Z) + E_B(Z + 1)] - rac{1}{2}[E_C(Z) + E_C(Z + 1)]$$

where $E_i(Z)$ is the binding energy of the $i$th level in the element of atomic number $Z$ and $E_i(Z + 1)$ is the energy of the corresponding level in the element of atomic number $Z + 1$. In this formulation, taking the averages of energies $E_B$ and $E_C$ for the elements $Z$ and $Z + 1$ is an attempt to account for the fact that these energies actually relate to the core level ions of element $Z$. A more accurate approach is described by Briggs and Riviere,$^{(8)}$ in which relaxation of the electron is taken into account, as is the interaction between the two final state holes.

Although these computational methods could be used to identify observed Auger transitions, compilations of Auger line positions are generally used for this purpose. Using data such as this, peak positions determined by the maximum negative excursion in the differentiated $(dN(E)/dE)$ spectrum provide sufficient information for the identification of all elements except H and He.

2.2 Ionization and Auger Transition Probabilities

As discussed later in section 3.4, two of the key factors in determining the intensity of a given Auger transition are the ionization cross-section $\phi_i$ and the Auger transition...
probability $\psi_i$. The product of these two terms gives a measure of the probability that the $i$th level of an atom will be ionized and that, once ionized, an Auger electron will be emitted. The Auger transition probability has already been considered in the context of its relationship to the XRF probability and is illustrated in Figure 3. The ionization probability will now be discussed.

Figure 4 shows a plot of the ionization cross-section as a function of the ratio $E_p/E_w$ where $E_p$ and $E_w$ are, respectively, the primary electron beam energy and the ionization energy of the initial level. Although $E_p/E_w > 1$ is required, it is clear that $E_p/E_w \sim 3$ is most efficient at producing ions.

In addition to the primary electron beam, many secondary electrons have sufficient energy to ionize atoms within the solid. This has the overall effect of enhancing ionization, particularly for surface atoms and levels with low ionization energies.

### 2.3 The Analysis Volume

A critical requirement in the interpretation of AES data is an understanding of the volume sampled by the technique. As illustrated in Figure 5, the primary electron beam may penetrate several microns into the solid. A fraction of these primary electrons are backscattered and emitted with some losses (e.g. the plasmon loss features in the secondary electron spectrum). Auger electrons may be excited throughout the penetration volume. As discussed below, however, only those Auger electrons generated within the first few layers of the solid can be detected. This is because of the restricted escape depth for Auger electrons. This situation contrasts sharply with the analysis volume for XRF, which essentially comprises the entire penetration volume. Auger electrons can also be emitted from the near surface layers outside the area that was directly irradiated by the primary electron beam.

This is due to dispersion of the backscattered electrons, which can also excite Auger electrons.

It is the limited escape depth or mean free path of the Auger electrons which is responsible for the surface sensitivity of the technique. Physically, this is due to the
strong interactions experienced by electrons as they pass through the solid. Figure 6 is a compilation of escape depth data for electron kinetic energies in the range of 2 to 1500 eV. This universal curve is frequently used in quantitative analysis; however, this neglects the variation in escape depth for different materials.

From this discussion, it is evident that the Auger sampling volume is not strongly dependent on the energy of the primary electron beam. The angle of incidence is, however, an important factor. In general, decreasing the angle of incidence from near normal to a low angle (from the surface) increases the analysis area/volume. Thus, varying the angle of incidence can increase the Auger signal for spot mode AES, but degrade the resolution in SAM.

3 INSTRUMENTAL METHODS

3.1 Electron Excitation

As mentioned earlier, the Auger process is initiated by irradiating a sample with electrons, photons, or ions. Since electrons are the most widely used Auger excitation source, this discussion will focus on electron sources (electron guns).

A simple electron gun design is shown in Figure 7. In this example, a filament or thermionic emitter is the source of electrons for the electron gun. Thermionic emitters produce electrons by heating a material (LaB₆, W, Ta, or thorium oxide) to temperatures that allow a portion of the material's electrons to overcome the work function barrier and escape into vacuum. Typical thermionic sources produce electron beam diameters in the millimeter range. Consequently, field emission sources can operate at or near room temperature. The resulting electron beam diameter is typically <1 micron in size. Although the smaller beam diameter would make field emission sources the source of choice, current stability issues can be a deterrent. Further, the work function and emission current are greatly affected by adsorption of gases on the field emitter tip. As a result, field emission sources require a highly controlled environment for operation.

Once the electrons are emitted into vacuum, they are extracted and accelerated from the emitting area via an anode. Focusing of the beam is accomplished through a combination of electrostatic condenser and objective lenses. Such lenses focus thermionic source beams down to a few microns in size, while field emission sources can be focused down to a few tenths of microns in size. Once focused, deflection plates are used to steer the beam. This allows the beam to be scanned/rastered over a surface in a manner similar to that used in scanning electron microscopy (SEM).

It should also be noted that electron guns utilizing electromagnetic focusing are available. These guns produce smaller beam diameters (20 nm for field emission sources and 50 nm for thermionic sources).

3.2 Electron Energy Analysis

Auger electrons are energy analyzed with one of three types of energy analyzers: cylindrical mirror analyzers (CMAs), concentric hemispherical analyzers (CHAs), or retarding field analyzers (RFAs). The CMA is possibly the most widely used analyzer for AES. The basic design of a CMA is shown in Figure 8. It consists of a coaxial electron gun, entrance aperture, two
coaxial-cylindrical electrodes, and a detector. Electrons passing through the entrance aperture enter an applied electric field between the coaxial cylinders. The inner cylinder is held at ground, while the outer cylinder has a negative voltage. The resulting field directs electrons in a parabolic path toward the detector. For a given negative voltage, only electrons within a small kinetic energy window are focused onto the detector. In this manner, the concentric cylinder design acts as an energy filter for the analyzer. By varying the voltage on the outer cylinder, the CMA sweeps through a specified range of the electron energy spectra. For a single pass CMA, the detector is located at the exit of the first stage. The detector is either a channeltron or electron multiplier.\(^{(8,12,14)}\)

Integral spectra \((N(E))\) are recorded by directly counting the number of electrons detected at each kinetic energy. If a small alternating current (AC) signal is superimposed on the ramp voltage of the outer cylinder, a lock-in amplifier can be used in conjunction with the detector to record derivative spectra \((dN/dE)\).\(^{(12)}\) Most modern Auger systems record data in the \(N(E)\) mode and use computer algorithms to differentiate the spectra for peak identification and other data analysis.\(^{(15)}\)

The acceptance angle, instrument transmission efficiency, and energy resolution are some of the key parameters associated with any energy analyzer. The single pass CMA has a large acceptance angle (42°). This contributes to its high instrument transmission. Energy resolution, \(\Delta E/E\), is usually on the order of 0.3–2%, depending on the electron kinetic energy. Adding a second stage of coaxial cylinders in series with the first stage can enhance the energy resolution. In this case, the focal point of the first stage becomes the entrance point for the second stage and the detector is located at the focal point of the second stage. Since this modified CMA has two stages of focusing electro-optics, it is called a double pass CMA.\(^{(8,12,16)}\)

The sample-to-analyzer or working distance is a very important parameter for CMAs because they are extremely sensitive to small changes in this parameter. This is because the sample must be positioned at the focal point to optimize the electron optics of the CMA. Studies have shown that changes as small as 0.5 mm in distance lead to noticeable shifts in the electron energy spectra and a significant drop in signal intensity.\(^{(8,16)}\) Positioning a sample at the focal point of the analyzer is obtained by aligning the elastic peak of the primary electron beam. The kinetic energy spectrum in the region around the primary electron beam voltage is monitored while the sample is moved along the \(z\)-direction (axial direction) of the analyzer. Adjusting the sample’s \(z\)-position causes shifts in the elastic peak’s energy. The system is considered in alignment when the elastic peak’s energy matches the primary electron beam voltage. For example, if a sample is positioned at the optimum working distance for an analyzer, the elastic peak generated from a 3 kV primary electron beam will be observed at 3000 eV. The working distance is also important because it may (or may not) limit the ability to simultaneously focus other diagnostic tools on the sample.

It should also be noted that not all CMAs are equipped with a coaxial electron gun. For vacuum systems where multiple techniques might be used, an external electron gun can provide more flexibility. An external electron gun also allows more flexibility for analyzing at different angles of incidence.

The CHA shown in Figure 9 consists of an input lens, concentric hemispherical electrodes, and a detector.\(^{(8,12,14)}\) The electron gun is external for this energy analyzer design. The input lens retards (reduces the kinetic energy of) electrons and focuses them on the entrance aperture to the hemisphere. The electric field produced between the inner and outer hemispheres acts as an energy filter and focuses electrons on the detector at the exit aperture of the hemispheres.

CHAs can be operated in two different modes. In the constant analyzer energy (CAE) mode, the voltage difference between the hemispheres is fixed. Consequently, the kinetic energy of the electrons that can pass through the analyzer (i.e., the pass energy) and the range of passable energies (\(\Delta E\)) is also fixed. In this case, a sweep through the energy spectra is obtained by ramping the retarding voltage on the input lens. The advantage of this mode is that analyzer contributions to peak widths will remain constant across the energy spectra.\(^{(8,14)}\)

In the constant retard ratio (CRR) mode, the potential difference across the inner and outer hemispheres is varied. This means that the pass energy is varied and the range of passable energies (\(\Delta E\)) also varies. However, the

![Figure 9 Basic design of a CHA. (Reproduced with permission from D. Briggs, J.C. Riviere Practical Surface Analysis: Volume I: Auger and X-ray Photoelectron Spectroscopy, eds. D. Briggs, M.P. Seah, © 1990 John Wiley & Sons Limited.)](image)
ratio of $\Delta E/E$ remains constant; the energy resolution is constant across the energy spectrum. Typically, CHAs used for AES are run in the CRR mode, while those used for XPS are run in the CAE mode. The acceptance angle and instrument transmission efficiency can be comparable to that of the CMA. The sensitivity to sample distance is lower than that of the CMA.\(^{8,12,14}\)

An RFA is shown in Figure 10.\(^{17}\) This design is based upon electron optics used for LEED from single crystal samples.\(^{12}\) The LEED/RFA consists of an electron gun, four grids, and a phosphor screen. G1 and G4 are held at ground potential, while G2 and G3 have variable negative potentials carrying an AC signal. A lock-in amplifier provides data in the $E\,dN/dE$ mode by processing the signal detected at the phosphor screen.\(^{17}\) This is the only mode of data acquisition for this type of energy analyzer. RFAs have good instrument transmission, CMA quality energy resolution, and large acceptance angles. The signal-to-noise ratio is rather poor, while the sensitivity to sample distance is comparable to that of a CHA.\(^{7,12}\)

3.3 Vacuum Requirements

One of the basic requirements for operating an Auger system is an ultra-high vacuum (UHV) environment. A number of factors contribute to this. First, the electrons from the source or sample must be able to reach their desired destinations (sample or detector) before colliding with gas molecules.\(^{12,16}\) Since the mean free path of a free electron is approximately 1 m at a pressure of $10^{-3}$ torr,\(^{16}\) Auger analyses could be carried out under relatively poor vacuum conditions. However, such pressures would adversely affect the lifetime of the filaments used in the electron sources. As a result, pressures below $10^{-5}$ torr are recommended for extended electron source lifetimes.\(^{16}\)

The reactivity of the sample being analyzed and the high surface sensitivity of AES are factors that must be considered. Reactive samples may be chemically altered by interactions with the ambient gas molecules (e.g., oxidation of metals). At $10^{-6}$ torr, potentially 1 monolayer (1 monolayer = $10^{15}$ cm$^{-2}$) of ambient gas adsorption could occur in a period of one second.\(^{18}\) Since the utility of the AES technique is based on its ability to examine only the first few atomic layers of a sample, this represents a serious problem. To minimize this effect, most Auger systems operate at pressures in the $10^{-8} - 10^{-10}$ torr range.\(^{8,12,16}\)

The instrumentation required to achieve such pressures is readily available from a variety of vacuum equipment vendors (see section 3.8). A typical vacuum system consists of a stainless steel chamber with a number of ports and attached pumping equipment. The dimensions of the ports are standardized, so equipment from virtually any vendor can be attached to the chamber. For a comprehensive review of standard vacuum equipment and instrumentation, please refer to the work of Harris.\(^{18}\)

3.4 Signal-to-noise Factors

There are a number of instrumental and sample factors that contribute to the measured signal intensity of an Auger transition. Equation (2) relates these parameters to the Auger intensity, $I$, for a specific transition $i$.

$$I_i = A i X_i N B \phi_i \psi_i R \lambda_i$$

Here, $A$ is the area irradiated by the electron beam, $i$ is the primary electron beam current density ($A/cm^2$), $X_i$ is the fraction of atoms producing transition $i$, $N$ is the atom density ($atoms/cm^3$) of the material, $B$ is the backscattering factor (>1) of the sample, $\phi_i$ is the ionization cross-section ($cm^2/atom$) for transition $i$, $\psi_i$ is the transition probability, $R$ is the surface roughness factor, $T_i$ is the transmission factor of the energy analyzer, and $\lambda_i$ is the energy dependent escape depth of the emitted electron.\(^{19}\)

Increasing the primary beam current will increase the measured intensity. However, using an excessively high current may cause electron beam damage of the sample surface. The backscatter factor is a representation of how well a material causes backscattering of the primary electrons. Increasing the number of backscattered primary electrons leads to a small increase in the measured Auger intensity and a substantial increase in the background (noise) signal. Similarly, the roughness factor, $R$, is a representation of how rough the sample surface is. This is an important factor to consider because rough surfaces cause more electron scattering than smooth surfaces. A larger portion of primary electrons is scattered away from the sample and more Auger electrons are scattered back...
into the sample. This has a two-fold effect on the electron energy spectra. The increased scattering of Auger electrons leads to a decrease in the Auger signal detected. The increased scattering of primary electrons leads to an increase in the background (noise) signal.

Sample charging is another factor that must be considered. During Auger analyses of insulating or semi-insulating samples, a negative charge can accumulate in the near surface regions. This adversely affects the electron energy spectra by causing Auger peak shifts and lineshape broadening. In addition, charging may significantly increase the background noise.

Fortunately, a number of options for counteracting the effects of charging exist. The simplest option involves lowering the primary beam current. This may lead to significantly increasing acquisition times so that the desired signal-to-noise ratio can be obtained. If the insulating material is a thin film on a semiconducting or conducting substrate, increasing the primary beam voltage may help. By increasing the beam voltage, a larger portion of the primary electrons may reach the film/substrate interface and be transported away by the sample’s connection to ground. The net effect is a reduction in the negative charge accumulation in the film. However, if the insulating film is thicker than the range of the primary electrons, increasing the beam voltage will only serve to enhance the charging effect. Another option is to perform the analysis at glancing incidence (i.e. primary beam incident at glancing angle with respect to sample surface). This option decreases the number of primary electrons that end up trapped in the insulating material. Recent developments in electron spectroscopy have shown that simultaneous sample irradiation by low-energy (10 eV) inert ions can significantly reduce, and in most cases offset, the effects of sample charging.

### 3.5 Point Analysis and Auger Mapping

The most common mode of Auger characterization is point analysis (spot mode analysis). Spot analysis usually provides the best signal and minimizes the effects of surface roughness. However, directing large currents into a small area can lead to electron beam induced chemistry/damage on the sample surface. Decomposition of polymers, desorption of adsorbates, oxidation, migration of mobile species, adsorption, chemical decomposition, and sample charging are some of the effects that have been reported. In some cases, decreasing the primary beam current can alleviate these effects. Another option is scanning the beam (line or area scan) across a region of the sample. For example, Pepper has shown that electron beam exposure of a diamond surface during Auger analysis can cause graphitization of the surface. By rotating the sample during analysis, Pepper effectively avoided prolonged exposures of a given analysis spot to the electron beam and remedied this problem. The disadvantage with this approach is that the Auger signal may decrease due to varying surface roughness and/or varying secondary electron yields across the sample. Figure 11 is an example of two survey scans acquired in spot mode.

Rastering capabilities also make it possible to monitor the intensity of a given Auger peak as a function of position (Auger mapping or Auger line scans). These techniques are very useful for looking at the spatial distribution of specific elements across a sample. Figure 12 is an example of how Auger mapping was used to look at the distribution of elements in a cross-section of a multilayered device. The transition from one metal layer to another is more clearly defined in the Auger maps than in the secondary electron image. It should be noted...
that Auger mapping can be extremely time-consuming. Each point on the map requires a number of sweeps over the Auger peak for each element of interest. The less time-consuming alternative is to perform an Auger line scan. Instead of mapping the intensity of specific elements for a whole field of view, the intensities of the elements are mapped for only a single line.

### 3.6 Sample Preparation

For most AES applications, the as-received surface of a sample has been exposed to air and is therefore covered with an “adventitious layer” of carbon and oxygen. As a result, a number of sample cleaning/preparation methods have been developed to produce a “clean” surface.

The most common method involves inert ion bombardment of the sample surface. Inert ions (Ar or Xe) are used because they will not chemically react with samples. The ions are created and accelerated toward the sample surface with an ion gun. The simple ion gun shown in Figure 13 creates ions by electron impact ionization of the inert gas. The gas is either introduced into the ionization volume of the gun directly or by introducing a backpressure of gas in the vacuum chamber. In the ionization volume of the ion gun, electrons are emitted from two hot filaments and accelerated toward an anode. Prior to reaching the anode, the energetic electrons collide with the gas molecules and ionize them. Once formed, the ions are accelerated away from the anode. The focusing lens(es) focus the ions into a beam and the deflection plates raster the beam over an area of the target. Most ion guns produce ions with energies in the 500–5000 eV range and beam diameters ranging from 5–100 microns. Low-energy (10–100 eV) ion sources and radio frequency source ion guns are also commercially available from a variety of vendors (see section 3.8).

Some of the effects associated with ion sputtering are knock-on processes, enhanced diffusion of a sample’s constituents, preferential sputtering, surface roughening, and chemical degradation of the sample. Knock-on refers to ions causing surface atoms to be driven into the sample. Diffusion can be enhanced by the energy being deposited into the sample during bombardment. Preferential sputtering occurs when constituents of differing collision cross-sections and/or sputter yields are present in a sample. The element with the higher sputter yield will be sputtered away at a higher rate than the element with the lower sputter yield. Surface roughening is an issue because ion sputtering can increase the surface roughness over a period of time. This effect can be virtually eliminated by rotating the sample during ion bombardment. In all cases, the resulting surface can give an erroneous representation of the original sample composition.

For soft metals, in situ cleaning can be accomplished by scraping the surface with a sharp edge or abrading the surface with a wire brush. For other samples, a fresh surface may be obtained by in situ fracturing/cleaving of the sample. Both methods require the use of additional vacuum accessories.

### 3.7 Depth Profiling

Depth profiling is a technique that combines AES with ion sputtering to provide compositional information as a function of depth. Depending on the mode of operation, Auger data can be acquired either simultaneously with the ion sputtering (continuous mode) or in alternating stages (alternating mode), using preset sputter times. Depth profile data is then recorded as a function of sputter time. Converting sputter time to depth can be accomplished in several ways. Once the depth profile is completed, the resulting crater depth can be measured by a surface profilometer. Then, assuming a constant sputter rate, the relationship between depth and sputter time can easily be determined. Figure 14 is an example of a depth profile where the depth indicated on the x-axis was determined from a profilometer measurement. For samples made of a well-characterized material (e.g. SiO2), sputter rates are readily available in the literature. In other cases, standards may be used to calibrate the ion gun etch rate for a given material. Currently, oxides and metal film standards of known thickness are commercially available.

### 3.8 Instrumentation Vendors and Systems

The following (Table 1) is a list of vendors that sell AES systems, components, and related vacuum accessories. For further information about their products, please contact them through the indicated website addresses. Their listing here should in no way be construed as an endorsement of their products or services. This list is provided for informational purposes only.
4 DATA ANALYSIS

4.1 Elemental Identification

As was discussed in section 2.1, Auger spectra are fingerprints of the density of electron states (DOS) for the elements present in a sample. Since the DOS are unique for each element, the Auger transitions are also element specific. When combined with the large database of existing Auger spectra (e.g. PHI or JEOL Handbooks), elemental identification is possible without the use of calculations. The minor differences between reference spectra are not enough to create confusion in identifying elements. Since Auger spectra of many elements contain multiple peaks, looking at all of the peaks associated with an element removes most of the ambiguity in identifying the elements that are present. Ultimately, any uncertainty can be removed by acquiring standard spectra with one’s own spectrometer.

4.2 Quantification of Data

Extracting quantitative information from Auger spectra can be a difficult process. The Auger intensity is dependent upon a number of parameters (see Equation 2), most of which are not sufficiently known. So, in practice, an approach utilizing elemental sensitivity factors, derived from comparisons of standard spectra, is used. Most Auger systems are supplied with a database of sensitivity factors relevant for that particular instrument. These factors provide reasonably accurate quantification results when data is acquired under the same conditions as those used for deriving the sensitivity factors. Again, more accurate results can be obtained by acquiring standard spectra with one’s own spectrometer (see section 4.3).

The most common method of determining peak intensities is the measurement of peak-to-peak height in the dN/dE spectra. The relative intensity and atomic concentration of an element i is then calculated using Equations (3) and (4), respectively.

\[ I_{ni} = \frac{I_{mi}}{S_i} \]  
\[ AC_i = 100 \times \frac{I_{ni}}{\sum I_{nj}} \]

</table>
For the $i$th transition, $I_i$ is the relative intensity, $I_{mi}$ is the measured intensity, $S_i$ is the relative sensitivity factor, and $AC_i$ is the relative atomic concentration (atomic %). The sum is over all elements detected.\(^{(23)}\)

While the use of peak-to-peak heights provides a reasonable estimate of the relative concentration of elements, a more accurate representation is achieved by integrating the area under an Auger peak in the $N(E)$ spectra.\(^{(12,16)}\) Subtracting out the background and correcting for resolution and loss features are required prior to integration. It should be noted that background subtraction can be a difficult task. Since most sensitivity factors are generated from peak-to-peak height data, integrated intensities must be related to peak-to-peak heights via a proportionality factor\(^{(24,25)}\) to avoid introducing more error in the quantification.\(^{(16)}\)

### 4.3 Calibration Using External Standards

Calibration of sensitivity factors for an Auger spectrometer becomes necessary when the accuracy and precision of quantification data are an issue. Making up standards of known compositions that approximate the sample under study is useful. Standards should be chosen to cover a range of compositions, such that the unknown sample’s composition falls within the calibrated range of the spectrometer. Analysis of the standards and the unknown sample should also be performed with all operating conditions held constant.\(^{(16)}\) For example, in recent Auger studies of boron and phosphorus doped germanosilicate glass, results produced from use of the PHI Handbook sensitivity factors conflicted with results acquired from energy dispersive spectroscopy (EDS) analyses of the same samples. As a result, a SiO$_2$ and a boro-phospho-silicate glass (BPSG) standard were analyzed. The oxide standard was used to calibrate the O sensitivity factor. The BPSG standard was used to calibrate the sensitivity factors for B, P, and Si in a matrix similar to the sample under study. Since a good germanosilicate standard was not available, the handbook value for Ge was used. Re-evaluation of the unknown sample’s data using the newly derived sensitivity factors and the handbook Ge factor provided results in good agreement with the EDS results.\(^{(26)}\) It should be noted that, despite the rigor of this approach, errors associated with drifts in primary beam current and variations in sample roughness are still a possibility.\(^{(16)}\)

### 4.4 Extraction of Chemical Bonding Information

The shape and position of an Auger peak are reflections of an element’s core-level energies and valence band density of states. Altering the bonding environment of the element induces a shift in the core-level energies and a redistribution of electrons in the valence band that directly affects the Auger peak position and lineshape for that element. As a result, analyzing the peak position and lineshape of a transition provides some chemical bonding information.\(^{(7,12,16)}\) Examples of shifts in peak position and lineshape changes for Si and C, respectively, are well illustrated in the literature.\(^{(7,8,23,27,28)}\) The elemental Si KLL peak is typically observed at 1619 eV, while the silicon dioxide Si KLL peak is shifted down to 1609 eV.\(^{(23)}\) This energy shift is large enough that identification of the bonding states for Si and SiO$_2$ are relatively easy. Auger spectra of various carbon compounds illustrate changes in lineshapes associated with changes in chemical bonding. Figure 15 shows the derivative spectra of graphite, diamond, and SiC standards. While the energy shifts are negligible, the lineshapes are distinctly different.

Quantification and identification of the chemical bonding information contained in AES data is a relatively new field. Factor analysis is one technique that has been used to quantify chemical bonding information.\(^{(29,30)}\) Establishing a database of literature in this area of analysis is an endeavor undertaken by a few technical journals (i.e. *Surface Science Spectra* or *Surface and Interface Analysis*). The reader is referred to these journals and the general literature (journals like *Surface Science, Surface and Interface Analysis, Journal of Electron Spectroscopy and Related Phenomena, and Journal of Vacuum Science and Technology*) as a source of future information in this regard.

### 5 APPLICATIONS

Initial use of AES was limited primarily to fundamental surface science applications of the technique. As
awareness and understanding of the utility of AES spread and as AES related equipment improved, the applications have expanded greatly. Through the past thirty years or so, AES has played an important role in the development of broad areas of surface and materials science. In the following discussion, examples of this work will be discussed.

5.1 Basic Surface Science

Surface studies using AES include analyses of adsorbed species bonding, sticking coefficients and surface reaction mechanisms, and surface segregation. In many cases, AES is combined with other analytical tools such as LEED, EELS, or thermal desorption spectroscopy (TDS). One example of this is the work of Kiskinova et al.\(^{(3)}\) on the adsorption of oxygen on an alkali metal-covered Ni(100) surface. In this study, AES intensities were used to follow the kinetics of oxygen uptake for various alkali metals and alkali metal coverages of the Ni(100) surface. Also, AES lineshapes were used to deduce information concerning the nature of the O–Ni bonding. It was shown that the effect of the alkali metals was associated with an increase of the electron charge distribution in the near surface layers. The overall effect was to increase the surface oxygen concentration and induce the formation of an oxide phase at lower oxygen exposures than for clean nickel surfaces.

In addition to studies of metal surface chemistry, considerable attention has been given to semiconductors. In an excellent review article, Yates and coworkers\(^{(32)}\) describe in detail the application of AES, TDS, and other surface science methods to the study of semiconductor surface chemistry. Further, there is an extensive literature relating specifically to silicon, gallium arsenide, and other semiconductors.

Drathen et al.\(^{(33)}\) have, for example, studied the composition and structure of differently prepared GaAs(100) surfaces using LEED and AES. They were able to determine that different surface structures were uniquely and sensitively correlated to the arsenic surface coverage. In this work, the quantitative determination of the arsenic surface coverage was obtained from AES peak intensities using a layer model and a calibration measurement on a cleaved GaAs(110) surface.

Leone and coworkers\(^{(34)}\) have characterized the structures and growth of gallium overlayers on Si(100) surfaces. By measuring AES peak intensities as a function of gallium exposure they were able to determine the growth mechanisms. They found that gallium grows epitaxially up to 5 monolayers at 300 K. For substrate temperatures in the range of 330–600 K, growth followed the Stranski–Krastanov mechanism. The types of surface structures observed were found to depend on the gallium surface coverage.

5.2 Materials Science

AES has played a vital role in the development of many aspects of materials science. This area spans a broad range including metallurgy, oxidation and corrosion science, polymer technology, ceramics and powder technology, composite materials, tribology, catalysis, and microelectronics. Even within these topics there are broad application areas which merit their own review article. Two representative AES applications of interest and significance to this general area are surface segregation and thin film growth.

An excellent overview of surface segregation and its influence on materials properties is provided by Johnson and Blakely.\(^{(35)}\) As a result of differences in bonding and lattice strain at the surface and in the bulk, the surface composition of a multi-component system may differ substantially from its bulk composition. This is known generally as surface segregation and it may occur at grain boundaries as well as free surfaces. At a free surface, segregation may alter the sticking coefficient or reactivity. At an internal grain boundary, segregation may alter the mechanical properties of the solid.

Harris\(^{(3)}\) was the first to use AES to observe the segregation of sulfur to the surface of nickel. In these studies, it was observed that sulfur, present at very low levels in the bulk, segregated to the surface when the sample was heated to temperatures in the range of 873 to 1173 K. Similar examples of impurity segregation are reported by Jenkins and Chung\(^{(36)}\) (sulfur in copper) and Taylor\(^{(37)}\) (sulfur and phosphorus in stainless steel).

Segregation of alloy components has also been of intense practical and theoretical importance. An example of this is the excellent work of Webber et al.\(^{(38)}\) on the segregation of copper in nickel. For temperatures in the range of 850 to 920 K, they measured the equilibrium surface composition for alloys of 5% and 50% copper using a combination of AES and XPS. This combination of techniques, with their slightly differing sampling depths, allowed them also to non-destructively depth profile the near surface layers of the nickel. In addition to providing insight into the segregation process, these studies also demonstrated the difficulty of establishing equilibrium in experiments where evaporation of one component (Cu in this case) may occur. This observation led Lawson and Stinespring\(^{(39)}\) to extend the segregation model of Hofman and Erlewein\(^{(40)}\) to include the evaporation process.

The use of AES in the study of thin film growth has also been extensive. One example of this is the investigation of SiC formation by Yates and coworkers.\(^{(41)}\) In these studies SiC was grown at temperatures in the range of 890–1140 K using C\(_2\)H\(_4\) at an effective pressure of 4.4 × 10\(^{-5}\) torr. At
AES IN ANALYSIS OF SURFACES

predetermined intervals, the growth was interrupted to perform AES, XPS, and ELS measurements. In later work, Stinespring and Wormhoudt extended these studies to include the use of other gas species (CH$_4$ and C$_3$H$_8$) for growth at temperatures as high as 1495 K. Based on such studies, it is possible to determine fundamental parameters, such as reaction rates, and to gain some insights into the mechanisms of chemical vapor deposition (CVD) processes used to synthesize materials.

AES has also been used extensively to investigate diamond thin film growth. Stoner et al. have used a combination of AES, XPS, and Raman spectroscopy to investigate bias enhanced nucleation of diamond during plasma assisted chemical vapor deposition (PACVD). By periodically stopping the growth and performing a variety of surface and bulk characterization measurements, they were able to gain considerable understanding of the overall sequence of events which occur as diamond is first nucleated and then grown on silicon substrates. In later studies, Lannon et al. performed detailed surface studies using AES to characterize the initial stages of diamond nucleation on silicon. In these studies, C KLL line shapes were analyzed using factor analysis and standards for graphite, silicon carbide, and diamond. Use of factor analysis followed the methods developed by Fuchs et al. to characterize the sp$^2$-C/sp$^3$-C ratios of a-C:H films and by Putz et al. to determine the W−C/sp$^2$-C ratios of tungsten carbide films.

ACKNOWLEDGMENTS

The authors would like to thank Adam Holyoake at J. Wiley & Sons for his assistance during the various phases of preparing this manuscript. The authors would also like to recognize Gary McGuire at MCNC for his encouragement and recommendations during the preparation of this work. Finally, we would like to thank our coworkers and loved ones for their patience and support throughout the writing process.

Differential reflectance spectroscopy (DRS) is a surface analytical technique. It uses ultraviolet (UV), visible, or infrared (IR) light as a probing medium. The interaction of light with "strongly absorbing materials", such as metals, alloys, semiconductors, etc. occurs in the first 10–20 nm. Thus the differential reflectometer probes 50–100 atomic layers into nontransparent solid surfaces. Because of the specific probing depth of light, DRS fills the gap between other surface techniques such as ion-scattering, Auger spectroscopy, and ESCA (electron spectroscopy for chemical analysis), which probe 1, 5, or even 20 monolayers, and X-ray diffraction (XRD) which probes as deep as 1–50 µm into a bulk material. The information gained by DRS is somewhat different from that obtained by the other surface techniques mentioned. A "differential reflectogram" reveals details about the electron structure around the Fermi surface. Specifically, the instrument allows the exact measurement of the energies which electrons absorb from photons as they are raised into a higher, allowed energy states. Since each material has a specific electron-band structure the measurement of the characteristic energies for electron "interband transitions" serves as a means for identifying these materials. Furthermore, investigation of any shift of these characteristic energies, which may be caused by the addition of solute elements to a solvent, by transformations, lattice defects, ordering, or the like, provides a deeper insight into the nature of the solid state. The application of DRS is, of course, not restricted to strongly absorbing materials such as metals, alloys, or semiconductors. Its strength has likewise been demonstrated in the identification and characterization of transparent or semitransparent surface layers as observed in thin-film corrosion products on metal substrates. DRS is used to scan two samples whose properties differ slightly. Thus, the main advantage of DRS over conventional optical techniques lies in its ability to eliminate any undesirable influences of oxides, windows, electrolytes, instrumental variations, and the like, owing to the differential nature of the technique. No vacuum is needed unless measurements in the vacuum UV are desired. Thus, the formation of a surface layer due to environmental interactions can be studied in situ. The measurements are fast: a complete differential reflectogram, that is, an automatic scan from the UV through the visible into the IR region, is accomplished in about 3 min.

1 INTRODUCTION

DRS, also often called differential reflectometry (DR) or differential reflection spectrometry, is a surface analytical technique. It uses photons as a probing medium (i.e. light, varying in wavelength from the near-UV through the visible to the IR region). The interaction of these photons with strongly absorbing materials such as metals, alloys, semiconductors, etc. occurs in the first 10–20 nm. Thus, DRS probes 50–100 atomic layers into nontransparent solid surfaces. Because of this characteristic probing depth, DRS fills the gap between other surface techniques such as ion-scattering, Auger spectroscopy, or ESCA, which penetrate 1, 5, or even 20 monolayers, and XRD, which probes as deep as 1–50 µm into a bulk material.

DRS scans two samples (rather than one) whose properties (e.g. the composition of an alloy) differ slightly. The light that is reflected from this sample pair eventually impinges on a light-sensitive device such as a photomultiplier tube (PMT). After electronic processing the signal thus obtained yields a "differential reflectogram"
which has the essential features of an optical absorption spectrum.

The information obtained by DRS is somewhat different from that gained by the aforementioned surface analytical techniques. Specifically, the characteristic peaks in a differential reflectogram represent the energies which electrons absorb from photons as they are raised from a lower, filled energy state into an upper, unfilled state. The peaks thus obtained are reasonably sharp; still, they are less pronounced than X-ray emission or Auger peaks, for example. This stems from the fact that the latter spectra are obtained by electron transitions between distinct, inner electron levels whereas optical spectra result from electron transitions between broad, outer electron bands. In other words, optical techniques, such as DRS, disclose photon interactions with valence (or conduction) electrons rather than core electrons and thus reveal details about the electronic structure around the Fermi surface. Since each material has a specific electron-band structure, the measurement of the characteristic energies for electron “interband transitions” serves as a means for identifying these materials. Furthermore, investigations of any shifts of these characteristic energies, which may be caused by the addition of solute elements to a solvent, by transformations, lattice defects, ordering, ion-implantation surface states, or the like, provide a deeper insight into the nature of the solid state.

The application of DRS is, of course, not restricted to strongly absorbing materials such as metals, alloys, or semiconductors. Its strength has also been demonstrated in the identification and characterization of transparent or semitransparent surface layers as observed in thin-film corrosion products on metal substrates.

The main advantage of DRS over conventional optical techniques lies in its ability to eliminate any undesirable influences of oxides, windows, electrolytes, instrumental variations, etc. upon a differential reflectogram, owing to the difference-forming nature of the technique. Thus, the signal-to-noise ratio is quite high, which renders the method extremely sensitive. No vacuum is needed, unless measurements in the vacuum UV are desired. Therefore, the formation of a surface layer due to environmental interactions can be studied in situ. Moreover, the measurements are fast: a complete differential reflectogram, that is, a continuous and automatic scan from the UV through the visible into the IR region, is accomplished in about 3 min.

Conventional optical reflection spectra (i.e. graphs that depict the ratio between the reflected and the incoming light intensities as a function of the photon energy) are often relatively featureless. In contrast, differential reflection spectra are distinguished by a sequence of pronounced maxima and minima which represent in certain cases the first derivative of a conventional reflection spectrum. This feature is experimentally obtained as already mentioned, by utilizing two samples whose properties differ slightly, and by employing a lock-in amplifier which provides the difference in reflectivity between these two nearly identical specimens. This will become clearer in section 2.

The present contribution describes the differential reflection spectrometer and its application to problems in solid-state chemistry, solid-state physics, electrochemistry, and materials science. It also provides the theoretical background used to interpret the experimental results by relating them to pertinent electron-band structures.

2 THE INSTRUMENT

2.1 Optics and Electronics

The differential reflection spectrometer (also called the differential reflectometer) measures the normalized difference between the reflectivities of two specimens which are mounted side by side, having virtually no gap between them. Alternatively, two slightly different parts of the same specimen may be chosen. The sample configuration depends on the particular case under investigation, as shown in section 2.4.

Unpolarized, monochromatic light, having a continuously varying wavelength, emanates from a double monochromator (illuminated, for example, by a high-pressure xenon source) and is alternately deflected to one or the other sample by means of an oscillating mirror (see Figure 1). This mirror vibrates at a convenient frequency such as 50 or 60 Hz. The cross-section of the light beam is rectangular and parallel to the boundary that separates the two samples. This beam sweeps over the two specimens perpendicular to the boundary, as shown schematically in the insert of Figure 1. The total area scanned is generally $2 \times 4\,\text{mm}^2$, but can be varied in size by regulating the voltage to the vibrator coil of the mirror and by changing the gap size of the exit slit of the monochromator. The light impinges on the sample pair under near-normal incidence. The exit slit of the monochromator is focused on these samples. Another focusing mirror, which is placed after the specimens, produces a magnified image of the vibrating mirror on a ground plate of fused silica which is placed a short distance in front of the face of a PMT. This plate diffuses the light falling on the PMT (whose sensitivity may vary over the surface), thereby minimizing the effect of the slight motion of the light spot that results from the oscillations of the vibrating mirror.
The signal from the PMT consists of a direct current (DC) component, modulated by a 60-Hz square wave. This output is split into two channels. One contains a low-pass filter which removes the 60-Hz square wave modulation from the original signal. Thus, the average of the reflectivity $R = (R_1 + R_2)/2$ remains. This signal is held constant by a servo which regulates the high voltage applied to the PMT. The other channel is fed into a lock-in amplifier which yields an output proportional to $\Delta R = R_1 - R_2$. The lock-in is tuned to the frequency of the oscillations of the mirror. A divider circuit forms the ratio of the two signals, thus providing the normalized difference in reflectivity $\Delta R/R$, which is fed to the Y-axis of an X-Y recorder or to a computer. A potentiometer attached to the scanning gear of the monochromator delivers a DC voltage proportional to the wavelength of the light or to the photon energy. This signal is applied to the X input of the X–Y recorder (or a computer). A differential reflectogram, that is, a continuous plot of $\Delta R/R$ versus wavelength, is thus generated automatically. A scan between 200 and 800 nm (1.6–6 eV) requires about 1–3 min, depending on the scanning speed selected. The sensitivity in observing the normalized difference in reflectivity is better than 0.01%.

Measuring $R_1$ and $R_2$ at the same time and forming the ratio between $\Delta R$ and $R$ eliminates possible influences from fluctuations of the line voltage. It also eradicates intensity variations in the spectral output of the light source, the spectral sensitivity of the detector and the spectral reflectivities of the mirrors. Further, owing to the difference-forming technique, all disturbances of the sample surfaces (such as roughness, oxidation, contamination, etc.) are eliminated as long as they are common to both sample parts.

An oscilloscope connected to the PMT output monitors the light which scans over the two samples. It allows a direct measurement of the normalized difference in reflectivities of the two specimens and reveals whether or not the light beam rests for an equal amount of time on each specimen. Any corrective measures can thus be performed.

In short, DRS is fast, sensitive and nondestructive and it provides a continuous absorption-type spectrum, does not require a vacuum or polarized light, and eliminates surface disturbances that are common to both specimen parts. The data can be recorded under near-normal incidence. The analog instrument described here can certainly be replaced by digital components in conjunction with a personal computer (PC).

2.2 Sample Holder

The samples are clamped or attached by double-sided tape on their back to a mounting stage which can be moved vertically and laterally. This allows a specific area on the sample surface to be selected and the two specimens to be centered about the scanning beam.

The circuit of the differential reflectometer is arranged to provide a positive peak in $\Delta R/R$ if the sample on top of the mounting stage has a higher reflectivity at a given wavelength. (As a matter of consistency, an alloy with a higher solute concentration is always placed on top. In corrosion experiments, the reference specimen is placed in the upper position.)
2.3 Other Designs

A differential reflectometer using the configuration described here has been demonstrated to be the most versatile and sensitive design, though other approaches have been proposed. In one case, a stationary light beam and a rotating stage on which the two specimens are mounted is used.\(^4\) The samples are then vapor-deposited on round substrates of equal size and placed in two matching holes in the spinning disk. The light beam scans a relatively large arc-shaped segment of the sample as well as a substantial portion of the blackened spinning disk. In another design, which utilizes a moving specimen stage, the samples are mounted on the vibrating ends of a tuning fork.\(^5\) A stationary set of samples\(^{1,2}\) has, however, several advantages: any sample size and sample configuration can be used; smaller areas can be investigated; the area to be studied can be specifically selected; measurements in vacuum or in an electrolyte (corrosion) are less of a problem; and differences in temperature, stress, or electric field can be effortlessly studied. Bulk specimens are essential when alloys of exact composition, high homogeneity, smooth surface, and small grain size need to be investigated, and if a good reproducibility of the results is required. Their solute content can be easily checked, using chemical or microprobe analysis. Bulk specimens may be polished by various methods, thus eliminating the rough surface that is often caused by annealing. Furthermore, small changes in compositional difference can be easily measured. (The latter point is particularly important to reduce possible variations caused by oxidation, and to obtain a more pronounced structure of the spectral dependence of $\Delta R/\mathcal{R}$.) Finally, bulk specimens can be heat-treated, rolled, and quenched to obtain ordered, disordered, or any other configuration.

2.4 Sample Preparation

The preparation of specimens to be studied by DRS varies somewhat with the type of experiments being carried out. For the investigations of alloys, for example, a combination of heat treatments and cold rolling is necessary to ensure absolute homogeneity of the alloy composition across the samples and to obtain a fine grain. Because of the high sensitivity of the differential reflectometer, even the smallest inhomogeneity may lead to structure in a differential reflectogram when the light beam is scanned across one sample only.\(^6\) Thus, it is common to apply a solution heat treatment for about 10 days at slightly below the solidus temperature, followed by cold rolling and recrystallization at a lower temperature for a short time. Two specimens containing the same type of solute but of slightly different composition (generally, not more than 1 or 2 atom % difference) are usually embedded side by side in the same metallographic mount. The sample pair is then polished using standard metallographic procedures (ending, for example, with 1 μm diamond polishing compound on felt cloth). Since both alloys undergo identical preparation procedures at the same time, and the difference in solute is small, any possible changes of the surfaces such as deformation, oxidation, surface roughening, etc. are nearly identical and subtract out due to the differential technique. The measurements can therefore be performed in air. Any oxidation or surface roughening of the alloys decreases the peak height only slightly, but does not alter the position of the peaks on the energy scale. Embedding and polishing the two specimens in a common mount has another important advantage: the two alloys are situated in the same optical plane, causing the reflected beams to reach virtually the same point on the PMT.

For oxidation studies, a pure metal (or only one kind of alloy) is used. Half of this specimen is covered (after polishing) with a protective lacquer, while the other half is allowed to corrode. After that, the lacquer is peeled off, leaving the corroded and uncorroded specimens next to each other. Since the metal substrate is common to both sides, the contribution of the substrate to $\Delta R/\mathcal{R}$ cancels out due to the differential nature of the technique if the corrosion product film is thin enough. Thus, the features in the differential reflectogram are essentially only those of the corrosion product.

For electrochemical corrosion studies a more advanced method is used. Rather than utilizing one specimen, the metal slab in this case is divided into two parts which are electrically insulated from each other by a thin insulating foil. Different potentials can then be applied to each side. For example, one specimen half may be held at the protective potential (reference) and the other at the corrosion potential. The main advantage of this technique is that neither the corrosion cell window nor the electrolyte solution affects the results because of the nature of the differential reflectometer. In situ studies are therefore effortlessly achieved without the use of a protective layer on the reference half and without removing the specimen from the corrosion cell for measurements.

For high-temperature oxidation studies, the entire specimen is corroded. Subsequently, the corrosion product is removed from part of the specimen by a “half polishing” technique.

Samples suitable for the study of ion-implantation damage are prepared by covering half of a commercial silicon wafer with a solid mask during the implantation process to shield that part of the underlying wafer from implantation. As a result, an implanted specimen next to a reference is readily obtained without having to deal with two separate samples and possible alignment problems. The light from the differential reflectometer is then scanned between these two specimen parts.
2.5 Related Techniques

DRS is a so-called “modulation spectroscopy” technique; such techniques provide the derivative of the spectral reflectivity (or of the imaginary part of the dielectric constant, $\varepsilon_2$) with respect to an external parameter.$^7$ The features obtained by modulation techniques are restricted to so-called critical-point interband transitions in the electronic band structure, i.e. they emphasize specific electron transitions from an essentially featureless background. This background is caused by many allowed electron transitions at a wide range of points in the Brillouin zone.

Most modulation techniques, such as DRS, wavelength modulation, thermoreflectance or piezoreflectance, are first-derivative techniques (Figure 2a). In semiconductor research, another modulation technique called electroreflectance is often used, which provides the third derivative of $R$ or $\varepsilon_2$. It utilizes an alternating electric field which is applied to a semiconducting material during the reflection measurement through either a Schottky barrier or a semiconductor/electrolyte junction.$^8$ The third derivative provides a set of three peaks for each interband transition (Figure 2b) whereas a first-derivative technique yields essentially only one (Figure 2a). A relatively involved line-shape analysis of electroreflectance spectra eventually yields the interband transition energies. In a first-derivative modulation spectrum, the lattice periodicity is retained, the optical transitions remain vertical and the interband transition energy changes with the perturbation (see insert of Figure 2a). In electromodulation, the formerly sharp vertical transitions are spread out over a finite range of initial and final moments$^9$ (see insert of Figure 2b). This causes the previously mentioned three peaks in an electroreflectance spectrum (Figure 2b).

A technique similar to DRS has been named reflectance difference spectroscopy (RDS).$^{10}$ Here, polarized light at near-normal incidence ($\alpha \approx 10^\circ$) is reflected from one sample only which is spun at 50 or 60 Hz in front of the light beam. This way any optical anisotropies that may exist on the sample surface have been shown to produce essentially identical absorption spectra to those from the two-sample technique described previously. However, optical measurements that involve sample motion are particularly sensitive to macroscopic imperfections that scatter light$^{10}$ and their general applicability is limited, as outlined in section 2.3.

Another technique related to DRS is called surface differential reflectivity spectroscopy (SDRS),$^{11}$ in this technique the sample to be investigated is placed inside a high-vacuum chamber and the reference sample is located outside the chamber. By switching the light beam between these two samples, the difference in reflectivity between clean (cleaved) and gas (air)-exposed surfaces is obtained as a function of the impinging photo energy.

The window to the vacuum chamber needs to be of high quality and also needs to be optically isotropic, since only one beam interacts with this window and it may otherwise introduce a characteristic spectrum by itself.

In the past decade spectroscopic ellipsometry (SE), featuring for example a rotating analyzer, has come of age.$^{12}$ This technique analyzes the elliptically polarized light which is reflected from a material. It yields the phase difference between the two mutually perpendicular, linearly polarized waves and the angle between these components (the “azimuth”). From these parameters the optical constants (index of refraction and damping constant or the real and imaginary dielectric constants) can be calculated for each wavelength. Besides being a nonderivative technique (section 2.1) this technique suffers from disturbances which affect the properties of the free surface, such as interactions with the environment, from mechanical deformation, polishing, native oxides, etc. As outlined in the literature$^{13}$ DRS offers some advantages over
SE, such as simplicity of the hardware, no need for polarization optics, and no need for precise optical alignment. Further, DRS requires only one optical window when in situ investigators are conducted, whereas SE needs two identical polarization-free optical-quality ports. DRS operates at near-normal incidence whereas in SE a 70° incidence is commonly used to increase the sensitivity.

2.6 Lineshape Analysis

As mentioned in section 2.1, the structure in differential reflectograms provides the energies which certain electrons absorb from photons when they are raised from lower, occupied energy states into higher, empty, and allowed energy states. Moreover, lifetime-broadening energies can be deduced from differential reflectograms. (The initial and the final states of interband transitions are generally not sharp, but are somewhat broadened because of the limited time an electron remains at an excited energy level.) The energies of the maxima in $\Delta R/R$ give in many cases a relatively good and sufficiently accurate value for interband transition energies. However, for more refined interpretations, a thorough line-shape analysis needs to be performed. This will be demonstrated now for the case of “compositional modulation” in which the solute content between two α-phase copper-based alloys is assumed to be different by a small amount (e.g. 1 atom %). The resulting differential reflectogram is then equivalent to the response from one sample having a composition $(x_1 + x_2)/2$ and which is modulated periodically by a compositional increment $\pm \Delta x/2$. As an example, Figure 3 depicts a differential reflectogram typically found for compositional modulation of many α-phase copper-based alloys. Four distinct maxima or minima are observed, which are labeled as peaks A through D. They are caused by interband transitions from d-bands below the Fermi level to free-electron-like $L_0^2$ bands just above the Fermi level, and by transitions from the same $L_0^2$ band into the $L_1$ band well above the Fermi level, as shown in Figure 4. The change $\Delta x$ of an alloy having the composition $x$ affects both types of transitions for the same reasons, which are (1) a shift of the energy bands, (2) a change of lifetime broadening, and (3) a shift of the Fermi level with respect to the bottom of the $L_2$ band. These shifts are indicated in Figure 4 by dashed lines. As a result of these perturbances, a change of the complex dielectric function occurs, as shown in Equation (1).

$$\Delta \varepsilon = \frac{d\varepsilon}{dx} \Delta x$$

(1)

This variation is related to the relative change $\Delta R/R$ by means of Equation (2),

$$\frac{\Delta R}{R} = \left( \alpha \frac{d\varepsilon_1}{dx} + \beta \frac{d\varepsilon_2}{dx} \right) \Delta x$$

(2)

Figure 3 Experimental differential reflectogram ($\Delta R/R$ versus photon energy $E$) for a Cu–1.5 atom % Ga alloy (average alloy composition: the two specimens consisted of a Cu–1 atom % Ga and a Cu–2 atom % Ga alloy respectively). (Reproduced from R.E. Hummel, R. Enderlein, Phys. Rev. B, 29(4), 1529–1533 (1984). Copyright 1984 by the American Physical Society.)

Figure 4 Schematic band structure around the L symmetry point for copper (solid lines) and an assumed dilute copper-based alloy (dashed lines). Pertinent electron interband transitions are shown by vertical arrows. Note: only the upper d-band is shown. (Reproduced from R.E. Hummel, Electronic Properties of Materials, 2nd edition, Figure 13.18, 1993. Copyright Springer-Verlag GmbH & Co.)
where \( \alpha \) and \( \beta \) are weighting factors, called the Seraphin coefficients\(^{13}\) and

\[
\varepsilon_1 = n^2 - k^2
\]

(3)

\[
\varepsilon_2 = 2nk
\]

(4)

\( \varepsilon_1 \) and \( \varepsilon_2 \) are the real and imaginary parts of the complex dielectric function\(^{16}\)

\[
\varepsilon = \varepsilon_1 - i\varepsilon_2
\]

(5)

Using the spheric parabolic band model one can write\(^{16}\)

\[
E_{d,s}(k, x) = E_{d,s}^0(x) + \frac{k^2 h^2}{2m_{d,s}}
\]

(6)

The Fermi energy is varied through solute additions according to

\[
E_T(x) = E_f^0(x) + E_s^0(x)
\]

(7)

where \( E_f^0(x) \) is the Fermi energy with respect to the bottom of the s-band. The interband part of the dielectric function, \( \varepsilon \) (which is assumed to be the only part relevant in the spectral region under consideration), is expressed by Equation (8).

\[
\varepsilon = -\frac{4\pi e^2|p_{sd}|^2}{\hbar w^2 m^2} \left[ \frac{d^2 k}{4\pi^2} \frac{f(E_d(k, x)) - f(E_s(k, x))}{E_d(k, x) - E_s(k, x)} + \frac{i\hbar}{\Gamma} \right]
\]

(8)

Here, \( f(E) \) is the Fermi distribution, \( p_{sd} \) is the interband momentum matrix element, and \( \hbar \Gamma \) the lifetime broadening energy. The derivative \( \frac{d}{dx} \) in Equation (8) in combination with Equation (2) yields Equation (9).

\[
\frac{\Delta R}{R} = A \frac{d}{dx} \left[ E^0_f(x) + E^0_s(x) \right] F \left( \frac{w - w_T}{\Gamma}, \theta \right)
\]

(9)

where

\[
F(s, \theta) = \sin \varphi \cos(\varphi - \theta)
\]

(10)

\[
\varphi = \arcsin \left( \frac{1}{\sqrt{1 + s^2}} \right)
\]

(11)

\[
A = \frac{kC}{\Gamma} \Delta \chi
\]

(12)

\[
\theta = \arctan \left( \frac{\beta}{\alpha} \right)
\]

(13)

and

\[
w_T = \frac{E_T}{\hbar}
\]

(14)

Equation (9) implies that \( \Delta R/R \) is proportional to the function \( F(s, \theta) \). Figure 5 depicts \( F(s) \) for different values of \( \theta \). Comparison of Figure 5 with Figure 3 shows that the experimentally obtained spectral dependence of \( \Delta R/R \) in the vicinity of peak A resembles the spectral dependence of \( F(s) \) for \( \theta \) values between 0° and 90°. For \( \theta = 90° \), \( F(s) \) is symmetrical about \( s = 0 \) and the peak energy \( E_m \) is equal to the transition energy \( E_T \). This type of curve is identical with the spectral dependence of \( \varepsilon_2 \) which is obtained by solving the classical Lorentz equation for harmonic oscillators.\(^{12}\) For \( \theta = 0° \), \( F(s) \) is asymmetrical about \( s = 0 \) and \( E_T \) lies in the center between minimum and maximum. This curve resembles the classical spectral dependence of \( \varepsilon_1 \) which is likewise obtained from the Lorentz equations. For features B and C in Figure 3, \( \theta \) may be assumed to be close to 0°, which leads to a transition energy somewhere between minimum B and maximum C. Experimental observations suggest that features B and C are indeed part of one transition: when the energies of peaks B and C are plotted versus the solute concentration, both curves are essentially parallel to each other.\(^{17}\) The inflection points in the curves of Figure 5 can then be used for the characterization of \( E_T \).

Most experimental differential reflectograms have curve slopes which suggest \( \theta \) values other than 0° and 90°. These \( \theta \) values and the appropriate transition energies \( E_T \) can be found by curve fitting in the following way. In Figure 6, part of an experimental differential reflectogram (in the vicinity of peak A) is shown. The minimum of \( (\Delta R/R) \) is used as the zero point of the vertical axis. Then three critical frequency values are extracted: \( w_m \) is the frequency at which \( (\Delta R/R) \) has its maximum value; \( w' < w_m \) is the frequency where \( (\Delta R/R)_{w'} = 1/2(\Delta R/R)_m \). Finally, \( w'' = w_m + (w_m - w') \). The ratio \( (\Delta R/R)_{w''}/(\Delta R/R)_m \) is a function of \( \theta \) only and is plotted in Figure 7. Once \( \theta \) is known, \( w_T \) (and thus \( E_T \)), can be found as a value between \( w' \) and \( w_m \) as shown in Equation (15).

\[
\frac{\Delta R}{R} \left| \begin{array}{c}
\right| w_T = \frac{1}{2} (1 + \sin \theta) \left( \frac{\Delta R}{R} \right)_m
\end{array} \right.
\]

(15)

The lifetime broadening can be calculated using Equation (16).

\[
\Gamma = (w_m - w_T) \tan \left( \frac{1}{2} \theta + \frac{\pi}{4} \right)
\]

(16)

For illustration, a lineshape analysis, as described above, has been applied to an experimental differential reflectogram for a copper–3.5 atom % aluminum alloy. Figure 8 shows the experimental spectral dependence of \( \Delta R/R \) in the vicinity of peak A (solid line) and some
calculated $\Delta R/R$ values (dots) for $\theta = 55^\circ$. The agreement is remarkably good. One can state therefore, with reasonable confidence, that peak A and the substructure around this peak are caused by electron transitions from d-band to s-states just above the Fermi energy level. Comparison of the experimental transitional energy $E_T$ with that deduced from calculated band diagrams suggests that peak A is caused by transitions from the upper d-bands to the Fermi energy level.

Experience has shown that the difference between $E_m$ and $E_T$ is usually only between 0.02 and 0.06 eV – a difference which is too small to be recognized in current

Figure 5 $F(s)$ versus $s$ for selected $\theta$ values ($s$ is proportional to the photon energy $E = \hbar w$). (Reproduced from Enderlein et al. by permission of Wiley–VCH Verlag.)
band calculations. Thus, the peak energy $E_m$ can be used in many cases as a good approximation for the true transition energy, $E_T$.

The lineshape in the vicinity of peaks B and C has also been analyzed by considering the $L_2^0(E_F) \rightarrow L_1$ as well as the $L_2 \rightarrow L_1$ transitions (Figure 4). Using transition energies and other variables as adjustable parameters, experimental differential reflectograms can be essentially reproduced.$^{(15)}$ The “hand fitting” exemplified here can certainly be replaced by analytical least-square methods run on a PC.

In summary, this section has demonstrated, for dilute copper-based alloys, that the structure observed in differential reflectograms can be utilized to extract the energies for electron interband transitions. This technique is, however, much more widely applicable, as will be demonstrated in the next section using a number of characteristic examples.

### 3 APPLICATIONS

The differential reflectometer has been successfully used in a number of research fields such as the study of the electronic structure of alloys,$^{(20)}$ order–disorder transformations,$^{(9,14)}$ and investigations of surface films,$^{(11)}$ corrosion,$^{(12)}$ and the effects of ion-implantation in semiconducting materials.$^{(17)}$ Some selected applications are presented here as an illustration of the capabilities of DRS in scientific research and non-destructive industrial production control.

#### 3.1 Investigations of the Electronic Structure of Alloys

The differential reflectograms for copper alloys containing zinc, gallium, aluminum, tin, silicon, or germanium are qualitatively similar.$^{(20)}$ Thus reflectograms of only one of these binary systems are presented and discussed in detail here as an example. In Figure 9, a series of $\Delta R/R$ versus $E$ curves taken on copper–zinc alloys are shown, in which the zinc content increases from top to bottom. The characteristic peaks A through D, mentioned in section 2.6, can be readily recognized. One observes immediately that the energies of these peaks shift with variation of the solute...
concentration. In particular, peak A, at about 2.2 eV, is seen to shift to higher electron energies. This peak was identified in section 2.6 as resulting from electron transitions between the upper d-bands and the conduction bands just above the Fermi surface. Specifically, they occur near the L symmetry point and also, to a lesser extent, near X and other points.\(^\text{21}\) In Figure 10, this shift in transition energy, \(E_T\), is shown (along with \(E_T\) values measured on other copper-based alloys) as a function of solute content, \(x\). Essentially a linear increase of \(E_T\) with increasing \(x\) is observed. The slopes are found to be steeper for solutes having successively larger electron-to-atom ratios (with the exception of copper–aluminum alloys).

The rise in energy difference between the upper d-band and the Fermi level caused by solute additions can be explained in a first approximation by suggesting a rise in the Fermi energy, which results when extra electrons are introduced into the copper matrix from the higher-valence solutes (rigid band model).\(^\text{22}\) The slopes in the \(E_T\) curves in Figure 10 are, however, considerably smaller than those predicted by the rigid band model. These results suggest, therefore, that the d-bands are likewise raised with increasing \(x\) and/or that the Fermi level is shifted up much less than anticipated. Band calculations\(^\text{23}\) substantiate this suggestion. They reveal that upon solute additions to copper, the d-bands become narrower (which results from a reduction of Cu–Cu interactions) and are lifted up as a whole. Furthermore, the calculations show that solute additions to copper cause a rise in \(E_F\) and a downward shift of the bottom of the s-band. Figure 4 reflects these results. Because of the lowering of the s-band, the Fermi level rises much less than would be expected if the s-band had remained constant.

An important characteristic of all \(E_T = f(x)\) curves is that the threshold energy for interband transitions, \(E_T\), does not vary appreciably for solute concentrations up to slightly above 1 atom % (Figure 10). Friedel\(^\text{24}\) predicted...
just this type of behavior and related it to “screening” effects. He argued that for the first few atomic percent solute additions to copper, the additional charge from the higher-valence solute is effectively screened and the copper matrix behaves as if the impurities were not present. The matrix remains essentially unperturbed as long as the impurities do not interact.

We turn now to electron transitions which cause peak D in the differential reflectograms and which take place when electrons absorb approximately 5 eV from the impinging photons. This peak involves transitions from the lower d-bands to the Fermi energy level\(^{(19,25)}\) (not shown in Figure 4). Thus, considerations can be employed that are similar to those used to explain the 2.2 eV peak. Two interesting variations should be pointed out, however. First, for photon energies around 5 eV, the \(\beta/\alpha\) ratio is negative (see section 2.6) which results in a lineshape that is inverted with respect to the one observed in the vicinity of peak A. Second, it has been found\(^{(20,26)}\) that in copper-based alloys in which the solvents possess a large valence electron concentration, the transition \(E_{d,\text{lower}} \rightarrow E_F\) is much more pronounced than in alloys containing solutes with a small number of valence electrons. (This may be attributed to an increase in the density of states of the d-bands at this energy for alloys with large valence electron concentration.)

For example, in Figure 11 (copper–arsenic), feature D is a sharp minimum, whereas in Figure 9 (copper–zinc) the same feature consists merely of a shoulder. Thus, copper alloys containing silicon, germanium, or arsenic are used preferentially to study the \(E_{d,\text{lower}} \rightarrow E_F\) transition.

In Figure 12, the energy of minimum D is depicted as a function of solute concentration for various diluted Cu-based alloys. This plot is similar to the one in Figure 10 which suggests that the lower d-band \(\rightarrow E_F\) transitions behave in a similar (but not identical) manner to upper d-band \(\rightarrow E_F\) transitions. Specifically, one observes only a very small shift in transition energy up to about 1 atom % solute, followed by a steady rise in interband energy amounting \(16 \times 10^{-2} \text{ eV per atom % solute}\). The slope in Figure 12 is about ten times steeper than in Figure 10 \((E_{d,\text{upper}} \rightarrow E_F\) transition) in which \(E_T\) increases by only \(1.2 \times 10^{-2} \text{ eV per atom % solute}\). This variation can only be attributed to a difference in the behavior of the upper compared with the lower d-bands. Thus, the results seem to indicate that the lower d-bands (not shown in Figure 4), at the points of origin for the electron transitions, move only small amounts upon alloying.

One more structural feature is contained in the differential reflectograms shown in Figure 9. It is of the \(e_1\) type (see section 2.6) and involves peaks B and C. This structure around 4 eV has also been ascribed in section 2.6 to transitions near the L symmetry point (see Figure 4\(^{(19,27)}\)). Chen and Segall\(^{(25)}\) found that the \(L_1'(E_F) \rightarrow L_1\) transition energy for pure copper is 4.26 eV, which is exactly halfway between peaks B and C (for low solute concentrations). This confirms the suggestion made in section 2.6 that the transitional energy contained in features B and C has to be taken at the inflection point between these peaks.

In Figure 13 the energy of peak B is shown to decrease sharply with increasing solute concentration, suggesting a strong lowering of particularly the \(L_1\) symmetry point due to alloying (Figure 4). Band calculations confirm this suggestion\(^{(28)}\). The transitions involving

Figure 13 Energy of peak B and shift in energy compared with pure copper as a function of composition for various copper-based alloys (Zn, Al, Ga, Sn). (Reproduced from R.J. Nastasi-Andrews, R.E. Hummel, Phys. Rev. B, 16(10), 4314–4323 (1977). Copyright 1977 by the American Physical Society.) A similar shift is found for peak C.

The conduction bands are affected by solute effects, for example lattice dilations. Different solute elements having different atomic radii must, therefore, influence the $L_2 \rightarrow L_3$ transitions in different ways. On the other hand, Figure 13 suggests that these transitions are also strongly influenced by the electron concentration of the solute: the decrease of the energy of peak B is more substantial for alloys which contain solutes with a larger valence electron concentration. Further, Cu–Ga and Cu–Al alloys, which possess identical electron concentrations per atom, behave alike.

It is important to note that in copper-based alloys, containing silicon, germanium, or arsenic, having solute concentrations of more than 1 atom % minimum B (that is, the 4.2 eV absorption edge) becomes less distinguishable (Figure 11), which may suggest that for higher electron concentrations the $L_2(E_F) \rightarrow L_1$ transition loses some strength.

One further piece of information can be taken from the differential reflectograms. It pertains to the “lifetime broadening energy”. The initial and the final states of any interband transition are generally not sharp, but are somewhat broadened because of the limited time an electron remains at an excited energy level (see section 2.6). This lifetime broadening can be calculated using Equation (16) and has been found to increase from $1.2 \times 10^{14}$ s$^{-1}$ for pure copper to $1.9 \times 10^{14}$ s$^{-1}$ for $\alpha$-phase copper alloys containing about 9 atom % of the solute.$^{20}$ The lifetime broadening energy $\hbar \Gamma$ also increases with increasing solute concentration (after an initial flat portion) up to approximately 1 atom % solute (Figure 14).

In summarizing this section, it can be stated that differential reflectometry is easily capable of identifying the electron transitions for copper–zinc and similar alloys. The results presented here confirm convincingly the findings that have been obtained by theoretical means. Furthermore, the information contained in Figures 9 through 14 add quantitative, experimental data about finer details of the changes in the electron configuration which happen due to the alloying process. We have seen that in the energy range between 1.5 and 6.2 eV electron transitions occur between the upper d-bands and the

Figure 14 Lifetime broadening energy $\hbar \Gamma$ calculated from experimental compositional modulation spectra for copper–aluminum alloys, as a function of Al concentration (see section 2.6). (Reproduced from Enderlein et al.$^{14}$ by permission of Wiley–VCH Verlag.)
Fermi energy level, between the lower d-bands and the Fermi energy level, and between some conduction bands.

In closing, it should be mentioned that differential reflection investigations have been also performed on copper–gold alloys,\(^{20}\) copper–nickel alloys,\(^{17,29}\) gold–iron alloys,\(^{30}\) nickel-based alloys,\(^{31,32}\) silver–aluminum alloys,\(^{33,34}\) and copper–cobalt alloys.\(^{35}\)

### 3.2 Atomic Ordering in Alloys

DRS is quite useful for the study of order–disorder phenomena. For these investigations, two specimens of the same alloy are utilized. One is in the ordered state, the other in the disordered state. The light beam of the reflectometer scans the two samples. This creates differential reflectograms which show peaks whenever the ordered state allows additional interband transitions.

In long-range ordered alloys, such as the extensively studied intermetallic phase Cu$_3$Au, the two kinds of atoms are periodically arranged on regular lattice sites and thus form a superlattice whose presence can be detected by additional X-ray lines, or measured indirectly by changes in hardness, resistivity, Hall constant, or other physical properties.\(^{36}\)

Ordering has a definite effect on the electronic structure of alloys.\(^{37–39}\) It has been proposed\(^{40}\) that the formation of a superlattice in Cu$_3$Au is accompanied by a folding of energy bands into a new, simple, cubic Brillouin zone which causes additional interband transitions.

Figure 15 depicts a differential reflectogram involving ordered versus disordered Cu$_3$Au. Several pieces of structure are observed. Firstly, a “down–up” curve between 3 and 4 eV, that is, an $\varepsilon_1$-type structure, is clearly visible involving a minimum at 3.29 eV and a maximum at 3.85 eV. As outlined in section 2.6, the energy for interband transitions for an $\varepsilon_1$-type structure is generally located near the center, i.e., between the minimum and the maximum, similar to those shown in Figure 5 for $\theta = 0^\circ$. For the case of Cu$_3$Au (Figure 15), this suggests a transition energy around 3.6 eV in complete agreement with conventional, that is, unmodulated, optical measurements.\(^{37–39}\)

This structure has been assigned to transitions from $\Gamma'_{\text{LSS}}$ to $X'_1$ (unfolded)\(^{5}\) or from the top of the Cu d-band to conduction band states near $\Gamma$.\(^{37}\)

Secondly, the maximum at 2.17 eV is of interest because its lineshape and peak energy closely resemble those observed for peak A for compositional modulation (Figure 3). It is suggested, therefore, that this peak is caused by transitions from the copper 3d-bands to s-states just above the Fermi level, similar to those depicted in Figure 4. Skriver and Lengkeek\(^{37}\) arrive at a comparable conclusion based on their relativistic energy band calculations. However, splitting of the s-bands at the point of the $d \rightarrow E_F$ transition is an alternative way for interpreting the peak at 2.17 eV.

Thirdly, weak structures occur near 3.13 and 5.3 eV in Figure 15. These peaks have comparable transition energies to similar peaks observed in compositional modulation spectra for copper–gold.\(^{20}\) They have been assigned to transitions from the Au d-bands and the lower Cu d-bands to the Fermi level, respectively, that is, to newly created transitions from the copper and gold d-bands to the Fermi surface.\(^{20}\)

Finally, it should be noted that $\Delta R/\bar{R}$ does not become zero at small energies, as it does for dilute copper alloys, which indicates electron transitions in the IR. This has indeed been observed.\(^{5,37}\) and has been interpreted to be due to high-lying energy bands close to the $\Gamma$ symmetry line.

A change of the degree of short-range order in solid solutions (for example in Cu–Al alloys) is more difficult to detect. Specifically, upon increasing short-range order only small variations in the previously mentioned physical properties occur. These variations take place concomitantly with a slight increase of the diffuse maxima in the continuous background of the diffuse X-ray scattering, typical for solid solutions.\(^{41,42}\) Figure 16 shows a differential reflectogram obtained on two copper–17 atom % aluminum alloys, which have different degrees of short-range order.\(^{43}\) Two pieces of structure are visible: a pronounced maximum at 2.64 eV and a broad $\varepsilon_1$-type shoulder in the vicinity of 5 eV. These features can be linked to interband transitions caused by short-range ordering since they are accompanied by the previously mentioned change.
in the diffuse X-ray background and do not occur in compositional modulation of these alloys.\(^{(43)}\) Comparison between Figures 15 and 16 indicates that the effect of short-range ordering on differential reflectograms (and thus upon the band structure) is about six times smaller than for long-range ordering.

Short-range order in Cu–Al alloys can also be characterized by a microdomain model in which the domains are 1–2 nm in size and are separated by diffuse boundaries that are enriched in one of the constituents.\(^{(44)}\) The microdomains consist of a two-dimensional antiphase shift structure resembling that for long-range ordered alloys. Further, an increase in short-range order raises the average number of next-nearest-neighbor solute atoms in relation to a matrix atom. In the present case the results can be interpreted as an increase of the next-nearest-neighbor Al concentration by about 0.4 atom %.\(^{(42,45)}\)

### 3.3 Study of Ion Implantation Damage and Epitaxial Regrowth in Semiconductors

Ion-assisted processes are widely used in semiconductor device fabrication, for example for doping. However, when highly energetic ions are implanted into a solid, some of the atoms near the surface are displaced from their regular lattice positions. This, in turn, causes a change in the electronic band structure. A differential reflectogram, obtained by scanning the light beam between an implanted and an unimplanted sample, therefore displays the characteristic interband transition peaks of the host material as we will see below. If no foreign atoms are involved, the peaks in the pertinent differential reflectogram are obviously caused by the lattice damage only.

Figure 17 shows a series of differential reflectograms taken on silicon samples, half of which were bombarded by silicon ions. The implantation energies varied between 60 and 180 keV while the implantation dose was kept constant.\(^{(46)}\) Three characteristic peaks in the UV region (which maintain their position on the energy scale) are observed in all diagrams. They are known to be due to interband transitions designated as \(L_3 \rightarrow L_1\) (3.4 eV), \(\Sigma\) region (4.2 eV) and \(L_0^* \rightarrow L_3\) (5.6 eV).\(^{(47)}\) This indicates that for all chosen implantation energies, a fair amount of implantation damage was introduced. Some differences in the UV peaks among the five graphs are noted, nevertheless: the heights of the UV peaks for the first three reflectograms are essentially identical.

**Figure 16** Experimental differential reflectogram of a more short-range ordered versus a less short-range ordered Cu–17 atom % Al alloy. The more short-range ordered state was achieved by quenching the alloy from 600 °C and storing it at room temperature for 42 h; the less short-range ordered state was accomplished by annealing at 290 °C after the 600 °C quench. (Reproduced from J.B. Andrews, R.J. Nastasi-Andrews, R.E. Hummel, *Phys. Rev. B*, 22(4), 1837–1842 (1980). Copyright 1980 by the American Physical Society.)

**Figure 17** Experimental differential reflectograms of Si\(^+\) ion-implanted silicon wafers. The dose was held constant at \(1 \times 10^{15}\) ions cm\(^{-2}\) whereas the implantation energy was varied as indicated. The individual curves have been shifted for clarity. The substrate consisted of a p-type Si single crystalline wafer whose resistivity was 5–10Ω cm. (Reproduced from Hummel et al.\(^{(46)}\) by permission of the American Institute of Physics.)
whereas the peak heights for larger implantation energies are observed to be smaller. This can be understood by knowing that with increasing implantation energies the radiation-damaged areas become amorphous, grow wider, and are eventually submerged below an essentially crystalline layer, as shown schematically in Figure 18. In other words, the height of the interband transition peaks indicates whether the information stems from the surface of the material or whether the signal comes from a submerged area. In the latter case the light that reaches the photosensitive device after reflection from the amorphous layer first has to pass twice through an essentially unperturbed surface layer where it is attenuated. In the present case the transition between the occurrence of a surface amorphous layer and a submerged amorphous layer (Figure 18) seems to occur at implantation energies between 100 and 120 keV, as deduced from Figure 17. This is confirmed by cross-sectional transmission electron micrographs.

The differential reflectograms depicted in Figure 17 contain additional vital information pertaining to the thickness of the amorphous layer. The broad peaks at low photon energies (labeled with Greek letters)

Figure 18 Schematic representation of the amorphous (A)/crystalline (χ) interfaces as a function of ion-implantation energy. Two examples are given in which the amorphous layer is (a) at the surface or (b) submerged below a crystalline layer. (Reproduced from Hummel et al. by permission of the American Institute of Physics.)

Figure 19 Calculated differential reflectograms obtained by applying the multiple-layer equations from classical optics and using literature values for the optical constants of crystalline and amorphous silicon. (Reproduced from Hummel et al. by permission of The Electrochemical Society, Inc.)

originates from interference effects and are caused by the path difference between the beams which are reflected from the top and from the bottom interfaces of the amorphous layer, respectively. Figure 19 depicts calculated differential reflectograms which have been obtained by applying the multiple-layer formulae from classical optics and by utilizing literature values for the optical constants of crystalline and amorphous silicon. These calculated reflectograms show that with increasing thickness of the amorphous layer, a given interference peak (e.g. α) shifts to lower energies. By comparing Figures 17 and 19, one can finally conclude that the amorphous layer grows in thickness with increasing implantation energy, quite in agreement with the current understanding and as depicted in Figure 18. A closer comparison reveals that the α-peak energy for the 60 keV implantation (Figure 17) and the α-peak energy for a 120 nm layer thickness (Figure 19) are nearly
identical, which suggests that in the present case a 60 keV bombardment causes a 120 nm thick amorphous layer, quite in agreement with cross-sectional electron micrographs.\textsuperscript{46}

In order to obtain the thickness of an amorphous layer from an experimental differential reflectogram, a diagram as shown in Figure 20 is useful. Here interference minima and maxima belonging to different orders as obtained from calculated differential reflectograms are depicted as a function of the wavelengths of their occurrence. As can be seen in Figures 19 and 20, each order is observed in a limited wavelength range only. To obtain the desired thickness from an experimental differential reflectogram, all available maxima and minima (of various orders) need to be matched to provide a unique thickness value from Figure 20.

It should be noted that for amorphous layers less than 5 nm thick, the first-order minimum starts to approach the onset of the interband transition peaks.\textsuperscript{52} In this case the thickness can be evaluated only with a lesser accuracy and it may be advantageous to replace the unimplanted reference sample by an amorphous one, thus obtaining an independent check of the thickness. This procedure eliminates the interband transition peaks (which mainly originate from the crystalline reference sample).

In summary, a single differential reflectogram provides several pieces of valuable information pertaining to the implantation-induced changes in a solid. Specifically, it is possible to conclude whether an implanted wafer is still crystalline, or damaged crystalline, or amorphous. Further, one can deduce the thickness of an amorphous layer and whether or not an amorphous layer is submerged. These parameters prove to be quite useful when a nondestructive production-line test needs to be conducted. A direct comparison of data obtained by DRS and by SE shows substantially comparable results. However, the presence of buried layers is not seen in SE\textsuperscript{13} (see section 2.5).

Ion implantation is generally used to provide electronic devices with the necessary doping elements to facilitate n- or p-type semiconductors. Detailed studies have shown that DRS is capable of providing quick and nondestructive information about the finer details of these manufacturing processes.\textsuperscript{51} As an example, Figure 21 depicts a series of differential reflectograms which were obtained after implanting As\textsuperscript{+} ions of different energies into a p-type (100) silicon substrate while holding the dose constant at 10\textsuperscript{15} ions cm\textsuperscript{-2}. It is observed that the interband transition peaks (to the right) remain at constant height, indicating that for all applied ion energies the amorphous region stays close to the wafer surface. This is expected, since heavy ions, such as arsenic, already encounter a relatively high fraction of nuclear stopping at the surface, thus displacing a large number of silicon atoms.\textsuperscript{53} We further observe in Figure 21 that the interference peaks, \(\alpha, \beta, \ldots\), move to the left with increasing implantation energy, thus confirming that the thickness of an amorphous layer increases with higher accelerated ion bombardment.

Similar experiments have been conducted by implanting light elements, such as boron (p-type), or by varying

---

**Figure 20** Calculated thickness values of surface amorphous layers for Si\textsuperscript{+} implanted silicon, plotted as a function of the wavelength of interference maxima and minima in differential reflectograms (see Figure 19). The curves represent various orders of interference, as indicated by the numbers in parentheses. (Reproduced from Hummel et al.\textsuperscript{51} by permission of The Electrochemical Society, Inc.)
Differential reflectance spectroscopy in analysis of surfaces

the implantation dose while keeping the implantation energy constant.\(^{(54)}\) For brevity, these studies are not shown here.

In general, the doping process is not completed by mere ion implantation. Instead, a well-designed annealing procedure has to follow which removes the damage inflicted on the lattice and which also activates the dopants. Figure 22 depicts a series of differential reflectograms which were obtained after several pieces of a silicon wafer (which had been previously implanted with 120 keV Si\(^+\) ions at \(5 \times 10^{15} \text{ cm}^{-2}\)), were isochronally annealed for 1 h at various temperatures. It is well known that annealing results in recrystallization, i.e. in a solid-phase epitaxial regrowth (SPER). Specifically, heating causes the amorphous/crystalline interface to move progressively through the amorphous region. (This is in contrast to a possible recrystallization process that would occur spontaneously throughout the entire damaged zone.) A recrystallization at the interface is plausible considering that the number of nucleation sites is substantially higher at the crystalline interface.

Figure 22 illustrates this in a vivid way: the shift of the interference peaks “\(\alpha\)” to the right, with increasing annealing temperatures, indeed shows a steady reduction of the thickness of the amorphous layer. The SPER is essentially completed after annealing for 1 h at 550°C. This is deduced by inspecting the appropriate differential reflectogram in Figure 22, which is observed to display no interference peaks in the low-energy region.

A supplemental piece of information can be obtained by studying the interband transition peaks in Figure 22. The heights of these peaks are observed to stay fairly constant up to 500°C, indicating that the surface remains amorphous up to this temperature. For annealings above 500°C, however, the interband transition peak heights become smaller, suggesting that the surface is now in the crystalline state. Some interband transitions are, however, still visible, implying that some residual defects remain. For temperatures higher than about 600°C,
the UV signals eventually disappear, indicating that any difference between the crystalline reference sample and the implanted and annealed specimen has finally ceased to exist. Similar experiments have been carried out for arsenic-implanted silicon in which several distinct annealing steps could be observed.\(^{52}\)

A comparable study has been conducted by implanting GaAs with He\(^+\) or Ar\(^+\) ions.\(^{55}\) Here, critical interband transitions at 1.42 eV (\(E_0\)), 1.7 eV (\(E_0 + \Delta_0\)), 2.9 eV (\(E_1\)) and at 3.2 eV (\(E_1 + \Delta_1\)) have been distinctly observed. To quantify the ion-implantation damage the area under the pertinent differential reflectograms has been evaluated around the (\(E_1 + \Delta_1\)) critical point. This procedure was repeated several times after the top 100 Å were chemically etched off in successive steps. (The interaction depth for light for the impinging plus the reflected beam is estimated at this wavelength to be about 60 Å.) The resulting damage-profile thus obtained compares favorably with a Monte-Carlo simulation of displaced atoms (trajectories of ions in materials, TRIM) as shown in Figure 23. In other words, DRS can be used to obtain implantation profiles in certain materials.

Morris et al.\(^{56}\) systematically extended ion-implantation studies of As, B, and BF\(_2\) into Si and compared their theoretical predictions of amorphous layer thicknesses (using the UT-MARLOWE software platform for Monte-Carlo simulations) with a number of techniques including DRS, transmission electron microscopy (TEM), scanning electron microscopy (SEM) and Rutherford backscattering spectroscopy (RBS). Good agreement has generally been found between the various techniques except for the B implants. It was assumed that the apparent measured thickness in the latter case may merely indicate a “depth of damage” rather than an amorphous layer.

### 3.4 Corrosion Optics

For the study of corrosion by DRS, one sample is usually a clean (e.g. electropolished) metal (reference) while the other is the same material which is additionally covered by a corrosion product. Corrosion products, particularly in their early stages, are generally thin and relatively transparent. Thus, the light from the differential reflectometer interacts entirely with this transparent or semitransparent film. Owing to the difference-forming nature of the technique, the effect of the underlying metal substrate is essentially subtracted out if the corrosion layer is thin enough. Thus, the resulting optical spectrum represents mainly the properties of the film alone with only minor contributions from the substrate. Therefore, DRS particularly identifies and characterizes the early stages of corrosion phenomena, which are less accessible by other methods such as X-ray techniques. Moreover, corrosion studies can be performed in situ, that is, in an electrolyte by utilizing a corrosion cell into which the light enters and from which it exits through a quartz window, as shown in Figure 24.\(^{57}\) For the experiments, a metal disk is divided into two halves which are electrically insulated from each other by a thin Teflon\textsuperscript{®} foil, thus permitting the application of a different potential to each subspecimen. This allows to produce the required two samples, one in the corroded state and the other electropolished.

As an example, Figure 25(a) depicts the differential reflectogram for Cu\(_2\)O. It is characterized by a pronounced maximum near 380 nm (3.25 eV) and several other peaks and shoulders as indicated in the figure. In contrast, the differential reflectogram of CuO is relatively featureless, displaying only weak shoulders in the vicinity of 560 nm (2.2 eV) and 360 nm (3.4 eV) which are superimposed on a steady rise in \(\Delta R/R\) towards higher photon energies (Figure 25b). In short, the differential reflectograms of these two oxide species of copper are clearly different from each other. We shall make use of this information in a moment.

Figure 26 depicts a series of differential reflectograms demonstrating the evolution of Cu\(_2\)O on a copper substrate in a buffered electrolyte of pH 9.\(^{60}\) After 10 min (0.17 h) the characteristic features of Cu\(_2\)O are already noticeable. The peak height near 380 nm, and thus the corrosion film thickness, initially grow rapidly. The growth rate, however, slows down as the film becomes thicker. The growth kinetics obey a logarithmic pattern.
relationship, as can be seen in Figure 27. This technique can be used to measure the activation energy for oxide formation under actual conditions.

The most common type of corrosion occurs when materials are exposed to the atmosphere or to water. For the investigation of this “free corrosion”, half of a polished metal disk may be covered with a protective lacquer, while the other half is permitted to corrode. After a specific time, the lacquer is stripped off and the sample is transferred immediately into the differential reflectometer. For in situ studies, a protective coating which is transparent in the entire spectral range (such as collodion) is applied to the reference sample and remains there during the entire measurement.

Copper exposed to the laboratory atmosphere for one day yields a differential reflectogram which contains the multiple peak structure characteristic of Cu$_2$O (Figure 28).\(^{(58)}\) The upward bend indicates, however, that some CuO is also present. With increasing time of exposure to air the reflectograms successively lose the Cu$_2$O peaks and tend to produce CuO patterns. This result is interesting, because the copper–oxygen phase diagram\(^{(59)}\) indicates that CuO is the stable species if copper is exposed to dry air below 375 °C. On the other hand, it has been suggested\(^{(59)}\) that CuO tends to be reduced to Cu$_2$O in the presence of metallic copper. The results obtained by differential reflectometry indicate the coexistence of different corrosion products, particularly in the early stages of corrosion, and the eventual formation of the equilibrium oxide. This is concluded from the superposition of the spectrum of one compound on the spectrum of the other.\(^{(57)}\)
Figure 26: Differential reflectograms depicting the in situ evolution of Cu$_2$O on a copper substrate in a buffered electrolyte of pH 9. (Reproduced from Hummel\textsuperscript{60} with kind permission from Kluwer Academic Publishers.) Both sample halves were initially held at the protective potential (−500 mV (saturated calomel electrode)) for 30 min (reflectogram marked 0 h). Subsequently, one sample half was held potentiostatically at −200 mV (saturated calomel electrode) and reflectograms were taken at the time intervals marked on the curves.

Figure 27: Growth kinetics of Cu$_2$O on copper substrate: evolution of the 380 nm peak of Figure 26 as a function of potentiostating time, $t$. (Reproduced from Hummel\textsuperscript{60} with kind permission from Kluwer Academic Publishers.)

Free corrosion of copper in distilled water again produces differential reflectograms which are indicative of mixed oxides of CuO and Cu$_2$O. The same observation is made when oxygen is continuously bubbled through water in which copper is immersed.\textsuperscript{58}

The question arises as to whether or not the thickness of a corrosion product can be estimated from its differential reflectogram. This is indeed possible when the optical constants (index of refraction, $n$, and damping constant, $k$) of substrate and corrosion product are known. Then, by applying the (rigorous) two-layer formulae\textsuperscript{49} the film-thickness-dependence of $\Delta R/R$ can be calculated. This has been done for CuO on a copper substrate and for NiO on a nickel substrate for wavelengths of 600 nm and 550 nm respectively, and for a film thickness range of up to 200 Å (see Figure 29).\textsuperscript{60} Utilizing this graph for the CuO film shown in Figure 25(b), one arrives at a film thickness of about 5 Å which is well within the accepted range. Some caution should be exercised, however, in applying Figure 29 too rigidly. The optical constants of thin films may not be exactly the same as those of the bulk. Nevertheless, an assumed error of 10% in the index of refraction also changes the film thickness by about 10%, which in the case described here is less than a monolayer and therefore negligible.

As a last example for the application of DRS in corrosion research, the phenomenon of dealloying is chosen.
Specifically, under certain conditions, such as exposure to aqueous solutions (e.g. a water faucet), copper–zinc alloys suffer a loss of zinc (by a mechanism called "selective leaching") which reduces their hardness. Based on visual inspection it has been generally assumed that copper alloys containing less than 15 atom % Zn are immune to dezincification.\textsuperscript{61,62} Differential reflectometry can effortlessly aid in the decision as to whether or not this statement is correct. To investigate dealloying, a surface technique is superior to chemical analysis, which averages bulk and surface values.

For the experiments described here, the reflectivity of a freshly polished specimen of the original composition is compared with that of a dealloyed specimen. Any difference in composition between the two sample halves should provide differential reflectograms similar to those in Figure 9.

Figure 30 depicts the spectral dependence of the difference in reflectivity between two copper–zinc alloys (one dezincified as stated in the caption of Figure 30, and the other in the virgin state) whose zinc content initially was 9.2 atom % (red brass). The reflectograms possess all the major features of compositional modulation, which suggests that red brass indeed undergoes dezincification. From the shift of peak A, a zinc loss of 3.8 atom % is found. (On the other hand, a Cu–21.4 atom % Zn alloy dezincifies under comparable conditions by losing 4.4 atom % Zn.) This smaller loss of zinc in red brass is, however, not the only difference compared with yellow brass (that is, Cu–Zn having a zinc concentration in excess of 15 atom %). The kinetics of formation of a specific peak height, and thus the corrosion rate, are about 16 times larger in yellow brass.\textsuperscript{63} Even a Cu–5.3 atom % Zn alloy dezincifies if potentiostated for long enough. The loss of zinc is in this case about 2.6 atom %,\textsuperscript{63} These experimental findings demonstrate once more the usefulness and sensitivity of DRS.

4 CONCLUSION

DRS has been shown over the past 30 years to be a highly sensitive, nondestructive, fast surface analytical technique which probes into solids between some monolayers up to 1 \( \mu \)m (depending on the material under investigation). Moreover, DRS is capable of characterizing and measuring the thickness of thin layers of, for example, corrosion films on bulk substrates or ion-implanted layers, whether they are on the surface or submerged below the surface. Moreover, DRS is distinguished by a low background noise and by an immunity towards surface disturbances (e.g. mechanical polishing, interactions with the environment, etc.) due to its difference-forming features. No vacuum is needed unless measurements in the vacuum UV are desired. The probing light does not to be polarized. DRS provides a continuous absorption-type spectrum from the IR through the visible into the UV spectral region. Its peak structure is caused by specific
interband transitions of the valence electrons, involving the electron band structure of the material under consideration.

The examples for applications of DRS given in this review emphasize only some major broad areas. Needless to say, DRS has also been used in a number of other investigations which cannot be easily summarized under a given heading. For the benefit of the interested readers, some more papers which utilize DRS are cited below.

Anodic oxide-film growth on GaAs has been studied in situ as a function of time utilizing only one wavelength (He–Ne laser). Structure changes in GaAs caused by Ar$^+$ ion bombardment are reported by Ludwig and Hummel. The DRS method has also been used to study InGaAs/GaAs and AlGaAs/GaAs quantum wells. The surface-state band gap of InP (110) has been investigated by surface differential reflectometry (see also section 2.5). Overall, it can be seen that in recent years DRS has been applied mainly to the study of semiconductors, particularly compound semiconductors.

ACKNOWLEDGMENTS

Dr V. Gerold (MPI Stuttgart) is thanked for his critical review of the manuscript. Likewise, Dr E.A. Irene (University of North Carolina at Chapel Hill) made several helpful suggestions. The development of DRS and its application in materials research would not have been possible without a steady stream of dedicated graduate students, such as J.A. Holbrook, J.B. Andrews, R.J. Nastasi-Andrews, W.M. Goho, W. Xi, C.W. Shanley, J.E. Finnegan, R.J. Smith, and F.K. Urban. The National Science Foundation has supported these investigations for many years.

1 INTRODUCTION

High-resolution EELS is an important technique for probing physical and chemical properties of surfaces. In an EELS experiment, a monochromatic beam of electrons is scattered from a surface, and the energy and momentum of the scattered electrons are determined. The energy and momentum exchanged between the incident electrons and the surface is related to electronic and vibrational excitations at the surface through various conservation laws, scattering selection rules and scattering mechanisms. EELS therefore provides a means of probing vibrational modes of adsorbed atoms, collective vibrational excitations of crystal surfaces (surface phonons), local electronic effects (negative ion resonances) and collective electronic excitations (surface plasmons). Vibrational modes of atoms and molecules adsorbed on surfaces reflect not only the species present, but also the structural and chemical effects associated with the surface–atom or surface–molecule bonds. EELS is therefore an important technique for gaining insight into atomic level processes that underlie chemisorption and chemical reactions at surfaces.
EELS experiments are generally carried out using incident electron kinetic energies in the range of a few to several hundred electron volts (eV). This is an important energy range for electron–solid interactions. The range includes energies sufficiently high to: (1) excite interband electronic transitions and collective electron excitations (bulk and surface plasmons), (2) observe and study energy dependencies of inelastic electron scattering mechanisms, and (3) observe effects resulting from electron diffraction; that is accessible energies include the energy range where the de Broglie wavelength of an electron, $\lambda_e$, becomes comparable to a typical crystal lattice constant $a$. When $\lambda_e \sim a$, and long-range surface atomic order exists, such as in a crystal, strong electron diffraction effects occur. Electron diffraction effects can affect EELS vibrational cross-sections, but more importantly, provide a basis for electron-based surface analysis technique. The development and extensive applications of EELS are documented in a book,\(^{(2)}\) review articles\(^{(3–6)}\) and the proceedings\(^{(7–14)}\) of a series of international conferences focused on vibrational properties at surfaces. The utility and broad application of the EELS technique in surface science is based on the various levels at which experimental data can be interpreted, and on the important feature that when applied to adsorbed surface species, EELS spectra directly identify molecular or chemical composition. While AES offers a highly sensitive means of detecting surface atomic composition (all elements except hydrogen and helium exhibit characteristic Auger spectra), it is unable to determine the chemical identity of adsorbed species unambiguously. AES, like electron spectroscopy for chemical analysis (ESCA), is an electron spectroscopy of electron energy levels in atoms. EELS is a molecular sensitive spectroscopy because vibrational excitations are functions of atomic composition, masses and chemical bond strengths and bonding geometry.

One level of interpretation of EELS spectra is based on the fact that many features of the vibrational excitations of molecules are essentially preserved when the molecules are adsorbed on a surface. This feature of characteristic vibrational signatures provides the basis for a powerful qualitative approach to EELS spectra analysis. Specific functional groups of atoms that make up more complex molecules exhibit characteristic vibrational signatures that can be used to identify these groups. The large body of vibrational data\(^{(15–21)}\) obtained using EELS and other vibrational spectroscopic methods, including Raman scattering and IRAS, can be used to identify the chemical nature of adsorbed species based on characteristic sets of vibrational excitations.

A second level of interpretation of EELS experimental data exploits symmetry selection rules that govern the scattering intensities. In many cases of practical interest, the molecular orientation, the local symmetry associated with an adsorbate vibration or the symmetry of a collective vibrational excitation (phonon) at the surface can be determined by noting the number of modes detected, or by examining the scattering intensity under various scattering geometries indexed to the crystal symmetries of the surface. Application of these techniques requires certain flexibility in the instrumentation as well as the capability to determine and orient crystal symmetry directions in relation to the scattering directions.

A third level of interpretation of EELS experiments is based on analysis of the full range of quantitative information available from an EELS experiment. Analysis of EELS data on this level deals with vibrational loss line widths and shapes, energy-and angle-dependencies of the scattering cross-sections and the information obtained from full use of the kinematic scattering relationships. Interpretation of EELS experiments on this level can yield realistic values for interaction potentials, local coordination and symmetry of adsorbate sites, and information about coupling between vibrational and electronic

---

excitations. The approach generally requires large-scale computational exercises in which the lattice dynamics are simulated, or in which the electron scattering is evaluated based on multiple scattering analysis similar to dynamical analysis of LEED beam intensities.

2 HISTORY

The detection of surface vibrational losses using inelastic electron scattering was first demonstrated by Propst and Piper in 1967. While the energy resolution of their EELS spectrometer was only about 50 meV, the experiments, which involved chemisorption of H\textsubscript{2}, N\textsubscript{2}, CO and H\textsubscript{2}O on W(100), clearly demonstrated the feasibility of probing vibrational excitations of chemisorbed species using electron scattering and established the high sensitivity of the method. Several years later, Ibach, using an improved instrument, reported observation of surface phonons on ZnO(1\textsubscript{1}00), and on Si(111). This was followed by work by several experimental groups including Andersson, Backx et al., Bertolini et al. and others, as well as a number of theoretical papers that presented formal electron scattering models providing a quantitative basis for exploiting the new technique fully. The advent of high-performance commercially available instruments based on those developed by Ibach and later by Kesmodel opened up the field to a broad range of surface scientists. The resulting enormous growth in published scientific work based on application of EELS techniques attests to the importance and popularity of this form of vibrational spectroscopy.

3 SAMPLE PREPARATION AND REQUIREMENTS

Application of EELS generally requires high quality single crystal surfaces. Collective surface vibrational modes (surface phonons) as well as the local vibrations of chemisorbed atoms and molecules are sensitive functions of the local structure and atomic coordination as well as the chemical environment. Lattice discontinuities, including surface steps, or the presence of impurity atoms, cause changes in vibrational excitation energies. EELS instruments are necessarily incorporated into UHV systems that generally also include surface preparation and characterization capabilities such as ion sputtering and sample heating for cleaning the crystal, and LEED and AES for probing surface crystal structure and chemical composition. A single crystal sample that yields a good EELS spectrum with narrow well-defined vibrational features. Many factors can broaden and shift vibrational loss peaks including substrate effects (steps, roughness) and chemical effects from impurity atoms, or coverage-dependent lateral interactions associated with chemisorbed atoms or molecules.

Clean and well-ordered surfaces can be prepared by a variety of methods. Many insulating or semiconducting crystals can be cleaved in vacuum yielding a clean well-ordered surface. Special flood gun techniques (described later) are required to deal with charging in cases where insulating samples are used. Some semiconducting surfaces can be passivated by chemical means and cleaned by simply heating the sample in UHV. Most metal crystals are prepared by cutting and aligning a suitable sample (typically 1 cm diameter × 1 cm thick) using spark wire or diamond saw technology followed by mechanical, chemical, electrochemical polishing and finally in situ cleaning using ion sputtering and/or high temperature annealing. Useful reviews of surface preparation, mounting and manipulation techniques are available.

4 ELECTRON SCATTERING MECHANISMS AND BASIS OF TECHNIQUE

The description of inelastic electron scattering can be conveniently divided into discussions that consider independently the scattering kinematics and conservation laws, and the scattering mechanisms.

4.1 Scattering Kinematics

Electron scattering from surfaces is governed by conservation laws and by several distinct scattering mechanisms. In certain cases involving high-symmetry geometry, selection rules can be used to draw conclusions about vibrational modes directly from general features of the scattering experiments. Single crystal surfaces are generally used in EELS experiments because translational invariance and geometrical uniformity of local adsorption sites are important requirements for interpreting experimental results within the framework of electron scattering models.

Figure 2 illustrates the parameters required to describe electron scattering from a crystal surface and introduces the notation to be used in following discussions. When an electron scatters elastically from the crystal (no energy exchange between the electron and the crystal), the conservation laws become the Laue diffraction conditions that govern diffraction processes, including LEED and reflection high-energy electron diffraction (RHEED),
where \( \mathbf{k}_s^i \) and \( \mathbf{k}_i^s \) represent the parallel component of scattered and incident electron wave vector, \( k_s^i \) and \( k_i^s \) represent the magnitude of the perpendicular component of scattered and incident electron wave vector, and \( \mathbf{G}_i \) is a surface reciprocal lattice vector.

When the scattering process involves the excitation of a single surface vibrational mode of energy \( h\omega \) and wave vector \( \mathbf{q}_i \), the conservation laws are, Equations (4) and (5):

\[
E_s = E_i \pm h\omega(\mathbf{q}_i) \quad (4)
\]

\[
\mathbf{k}_s^i = \mathbf{k}_i^s \pm \mathbf{q}_i + \mathbf{G}_i \quad (5)
\]

where \( E_s \) and \( E_i \) are, respectively, the scattered and incident electron energy. The scattering process can create or annihilate a phonon corresponding to the \( - \) and \( + \) signs. The relative probability of phonon creation and annihilation is governed by the Bose–Einstein statistics obeyed by phonon excitations. The gain-peak intensity at energy \( h\omega \) in an EELS experiment is proportional to the number of occupied vibrational states having energy \( h\omega \), which is proportional to the Bose factor \( \exp(-\hbar\omega/kT) - 1 \)^{-1}. The intensity of the corresponding loss peak is proportional to \( 1 + n \). Therefore the ratio of gain-peak to loss-peak intensity is given by \( n/(1 + n) = \exp(-\hbar\omega/kT) \).

Figure 3 presents a typical EELS spectra showing loss and gain peaks associated with excitation of a surface phonon on the Ni(100) surface at a specific value of \( \mathbf{q}_i \).

An electron can excite or annihilate more than one phonon through a sequence of single-phonon scattering events. A two-phonon scattering event is described by Equations (6) and (7):

\[
E_s = E_i \pm h\omega(\mathbf{q}_i) \pm h\omega(\mathbf{q}_j) \quad (6)
\]

\[
\mathbf{k}_s^i = \mathbf{k}_i^s \pm \mathbf{q}_i \pm \mathbf{q}_j + \mathbf{G}_j \quad (7)
\]

where \( \mathbf{q}' \) is the wave vector associated with a second scattering event. For multiphonon process involving excitation or annihilation of two or more phonons the number of variables exceeds the number of constraints represented by the conservation laws, and a continuum of loss/gain energies exists for each value of \( \mathbf{k}_s^i \). While single-phonon loss processes yield unique loss/gain peak energies for a prescribed scattering geometry (\( \mathbf{k}_s^i \) and \( \mathbf{k}_i^s \)) corresponding to branches of the phonon dispersion curves, multiphonon processes yield a broad continuum.

Fortunately, in most cases, single-phonon peaks are easily resolved above the multiphonon background (see Figure 3).
Figure 3), and measurements of the peak energies as a function of momentum transfer $\Delta k = k_i - k_s$ can yield the energy–momentum (dispersion) relations of phonon excitations. The dispersion relation ($h\nu$ versus $q$) contains useful information about interaction potentials associated with surface atoms.

### 4.2 Scattering Mechanisms

The conservation laws Equations (1–7) specify the constraints that govern a scattering event, but do not provide any information about the probability that a specific scattering event will occur. EELS peak positions are determined by phonon dispersion curves, and conservation laws and the relative strength of loss and gain peaks are governed by the temperature-dependent probability that a specific vibrational energy level is excited. In order to predict the peak intensities for phonon or other vibrational excitations at the surface, an understanding of the scattering mechanisms is required. Four unique scattering mechanisms have been identified that account for various observations of inelastic electron scattering from surfaces. (3–6)

#### 4.2.1 Dipole Scattering

Most EELS experiments are carried out using specular scattering geometry ($\theta_i = \theta_s$ and $\phi_i = \phi_s = 0$) and using low incident energies, $E_i \sim 1–10$ eV. Under these scattering conditions the dipole scattering mechanism usually accounts for the major contributions to EELS peaks. Dipole scattering theory has been discussed extensively in the literature. (30–37) The basis of dipole scattering is the interaction of the incident electron and its image charge (which produce a dipole field) with long-range electric fields produced by electronic or vibrational excitations. An important characteristic of the dipole scattering mechanism is that the angular spread of scattered electrons is small and approximately equal to $h\nu/E_i$, where $h\nu$ is the excitation energy (loss energy) and $E_i$ is the incident electron energy. The nature of the dipole scattering mechanism leads to inelastic scattering processes occurring away from the surface (typical distances $\sim 100$ Å) either before or after (specular) elastic scattering at the surface. The excitation probe depth of dipole scattering is of the order of the characteristic screening length for electrons in the material which is of the order of 1 Å for metals.

Dipole scattering formalisms can be applied to inelastic scattering resulting from adsorbate vibrations, surface phonons, and electronic excitations including electronic transitions and surface plasmons. The narrow angular spread of scattered electrons (or equivalently the small momentum transfer) associated with dipole scattering renders this mechanism of limited use in studying surface phonons away from the center of the two-dimensional Brillouin zone. When electronic excitations near the surface dominate the inelastic scattering, formulations of dipole scattering in terms of the dielectric response function (44–48) are useful. It has been shown that dielectric response determined by EELS compares well with that obtained from optical techniques. In semiconductor materials, where electron densities are low, loss energies are small ($\sim 1$ meV) and measurements of the width of the quasi-elastic peak interpreted using dielectric response models provide a useful means of probing low-energy excitations at semiconductor surfaces.

#### 4.2.2 Impact Scattering

A second scattering mechanism that dominates surface inelastic electron scattering at higher incident energies and is characterized by large-angle scattering (large momentum transfer) is known as impact scattering. (38,39) The existence of this scattering regime is well known from inelastic scattering from gas phase molecules (49) where image charge effects and long-range dipolar interactions do not exist. The diffuse background observed in LEED experiments (22,23) is another manifestation of a large-angle scattering mechanism. The temperature-dependent diffuse background exhibits energy-dependent angular patterns that reflect the crystal symmetry, suggesting that useful information is contained in the diffuse scattering spectra and angular distributions. Figure 4 displays the calculated incident energy dependence of the inelastic electron scattering cross-section of $S_1$ and $S_4$ phonons (see Figure 3) for Ag(100) under specific scattering conditions prescribed by $\Delta q_i$. It is clear that the cross-section varies substantially ($S_1$ varies over a factor of 100) over the energy range of interest. Such calculations are very useful in interpreting experimental data when closely spaced phonon energies are probed as in Figure 3. The excitation probe depth for impact scattering is governed by the inelastic mean free path of electrons in the material at the incident energy, $\lambda_c(E_i)$.

#### 4.2.3 Negative Ion Resonances

Temporary trapping of an incident electron is an important mechanism in vibrational excitation of a gas phase molecule. Strong coupling to various decay channels associated with a molecule adsorbed at a surface tends to oppose the formation of negative ion resonances in surface electron scattering (50) however, various experiments (6,51–53) have shown that negative ion resonance scattering exists for both physisorbed and chemisorbed molecules. Negative ion resonance scattering is characterized by an incident threshold energy and broad angular distributions characteristic of short-range interactions. Negative ion resonance scattering can
Beam energies at which LEED beams incident at the $X$ point of Ag(100) (with permission from J.L. Erskine, E.-J. Jeong, J. Yater, Y. Chem and S.Y. Tong, ‘Detection of Odd-symmetry Shear Modes at Metal Surfaces by Inelastic Electron Scattering: Experiment and Theory’, J. Vac. Sci. Technol., A8, 2649, 1990.) The rapid energy variation versus kinetic energy results from multiple scattering.

Calculated EELS impact scattering energy-dependent cross-section for even ($S_1$) and odd ($S_3$) symmetry phonons at the $X$ point of Ag(100). (With permission from J.L. Erskine, E.-J. Jeong, J. Yater, Y. Chem and S.Y. Tong, ‘Detection of Odd-symmetry Shear Modes at Metal Surfaces by Inelastic Electron Scattering: Experiment and Theory’, J. Vac. Sci. Technol., A8, 2649, 1990.) The rapid energy variation versus kinetic energy results from multiple scattering.

4.2.4 Surface Resonance Scattering

Electron diffraction from a crystal surface can lead to elastic (and inelastic) scattering resonances in which the electron is temporarily trapped in a propagating surface state above the vacuum level.\(^{54–61}\) The Laue conditions, Equations (1–3), can be solved for the threshold incident beam energies at which LEED beams incident at $\theta_i$ emerge from the crystal, Equation (8):

$$E_{th} = \left( \frac{G}{0.512(1 + \sin \theta_i)} \right)^2 \text{ (eV)}$$

where \((2\pi/\hbar)^2 = 0.512 \text{ eV } \text{Å}^{-1}\) and \(G = 2\pi/a \text{ Å}^{-1}\) is a reciprocal lattice vector. Electrons in these surface resonance states can suffer inelastic losses. Experimental evidence for this loss mechanism is well established,\(^{62–65}\) and theoretical treatments\(^{66,67}\) of the surface resonance loss mechanism are available.

4.3 Scattering Cross-sections and Selection Rules

Analysis of the energy- and angular-dependent scattering cross-sections generally requires detailed numerical calculations. Multiple scattering is strong in the energy range \((20–300 \text{ eV})\) generally used in inelastic electron scattering experiments, therefore, the phonon loss scattering cross-sections exhibit prominent and numerous peaks similar to those observed in LEED intensities. The symmetry of the crystal and the scattering conditions can often lead to predictions of scattering nulls without extensive calculations. The scattering nulls and general characteristics of scattering cross-sections imposed by symmetry are called selection rules.

Dipole scattering cross-sections\(^{(30–37)}\) are proportional to the strength of surface dynamic dipole moments. Dipole scattering generally dominates inelastic loss mechanisms at low incident energies \((1–10 \text{ eV})\) when losses are measured in specular scattering geometry. A dipole oriented perpendicular to a metal surface induces an image dipole that enhances the dipole field, whereas a dipole oriented parallel to the surface induces an image dipole that tends to cancel the field of the original dipole moment. This reasoning leads to the dipole selection rule that states: dipole scattering probes primarily surface vibrational losses associated with dynamic dipole moments oriented perpendicular to the surface.

The impact scattering mechanism,\(^{(38,39)}\) in principle, permits probing vibrational modes of all symmetries and orientations using EELS. However, impact scattering cross-sections tend to be one to two orders of magnitude weaker than dipole scattering cross-sections. Selection rules\(^{(68)}\) govern null scattering conditions for impact scattering. For example $x$-polarization modes (Figure 2) having dynamic displacements perpendicular to the scattering plane cannot be observed in a scattering experiment with $\phi_i = \phi_s = 0$ if the crystal has reflection symmetry about the scattering plane. Similarly, odd symmetry ($S_3$) phonon modes, for example (Figure 3), cannot be observed in a scattering geometry in which $\phi_i = \phi_s = 0$. Table 1 summarizes scattering selection rules for parallel (in-plane) mode vibrations.

5 INSTRUMENTATION

Figure 5 presents a schematic diagram of a high-performance commercial EELS instrument (adapted from technical information furnished by L.L. Kesmodel, L.K. Technologies Inc., Bloomington, Indiana, USA). The monochromator is designed to deliver a beam of electrons having a narrow angular width and energy spread to the sample. Scattered electrons are detected in an analyzer with high angular and energy resolution. Important parameters that characterize EELS instrument performance include energy and angular resolution, range of energy and scattering angles, monochromator current, analyzer sensitivity, background counting rate, and stability. Numerous technical articles, and a book contain material covering all aspects of the theory, design, construction and optimization of EELS monochromators, analyzers and integrated instruments. This section only covers the most basic features of EELS instrumentation in relation to intended applications.

State-of-the-art commercially available instruments have achieved energy resolution exceeding 1 meV under ideal conditions. High-performance instruments currently available achieve specifications listed in Table 2 (adapted from technical information furnished by L.L. Kesmodel, L.K. Technologies Inc., Bloomington, Indiana, USA). These performance specifications cover essentially all of the requirements for EELS studies of adsorbate vibrations, electronic excitations, and surface phonons.

fwhm, full width at half maximum.
EELS studies of surface adsorbates are generally carried out at low incident electron beam energies, $E_i < 10$ eV, and using specular scattering geometry, $\theta_i = \theta_s, \phi_i = \phi_s = 0$. Under these conditions, the dipole scattering cross-section is maximized and very high detection sensitivity can be achieved, i.e. $10^{-3}$ monolayer of CO can be detected. Angular resolution is generally not a concern in this regime because dipole scattering is sharply peaked along the specular direction. EELS studies of surface phonon (and plasmon) dispersion relations require higher incident energies and also require attention to the angular spread of the incident beam and analyzer angular acceptance. Measurement of energy losses at large momentum transfer (corresponding to a Brillouin zone boundary $\Delta k \sim \pi/a \sim 2.5 \text{Å}^{-1}$) requires higher energies: the momentum transfer associated with a surface phonon loss (where $\Delta E/E_0 \ll 1$) is governed by Equation (9):

$$\frac{2m}{\hbar^2} E_i (\sin \theta_i - \sin \theta_s) = \Delta k$$

where $E_i$ is the incident energy, and $\theta_i$ and $\theta_s$ are the incident and scattering angles. Evaluation of Equation (9) for a range of incident energies reveals that the entire Brillouin zone of a typical crystal can be accessed at $E_i = 200$ eV with a relatively small scattered electron angular range (15°) whereas for $E_i \sim 10$ eV, a much larger (and partially inaccessible due to mechanical constraints) angular range $\sim 70°$ is required.\(^{(14)}\) Formulas for calculating uncertainties in $\Delta k$ as a function of the finite angular acceptance of the analyzer and monochromator beam width are given by Ho.\(^{(5)}\)

Several groups have developed EELS instruments for specialized applications. Ho has developed an EELS instrument optimized for time-resolved studies.\(^{(75–77)}\) This instrument incorporates a high-speed multichannel detection system that permits an EELS spectrum to be measured on short timescales (<100 ms). Erskine has developed an EELS instrument having more geometrical flexibility (monochromator and analyzer on independent orthogonal rotation goniometers) that permits inelastic scattering studies using a broad range of incident and scattering configurations.\(^{(70,78)}\) High sensitivity (50 channels) and resolution of 2.5 meV is achieved using multichannel detection.

### 6 APPLICATIONS TO INTRINSIC PROPERTIES OF SURFACES

Principal applications of EELS techniques to surface analysis are outlined in this and the following section which divide the surface properties evaluated into intrinsic properties of a clean surface, and more complex systems in which a chemical adsorbate is present.

#### 6.1 Fuchs–Kliewer Phonons

Polar surfaces of ionic crystals (ZnO (1T00) and GaAs(1T00) for example) exhibit infrared-active longitudinal optical surface phonons known as Fuchs–Kliewer phonons.\(^{(79)}\) Some of the earliest work demonstrating the sensitivity of EELS to surface phonons was carried out on these surfaces.\(^{(25,26)}\) The signature of these phonons is a series of intense, equally spaced loss peaks having intensities described by a Poisson distribution. Loss and gain peak intensities scale according to Bose–Einstein statistics as expected.

#### 6.2 Bulk Phonon Resonances at Metal Surfaces

Certain metal surfaces (i.e. the (110) surfaces of face-centered cubic metals) exhibit strong surface resonances.\(^{(4,5,80,81)}\) The resonance is a result of a longitudinal bulk phonon that produces a dipole active mode with a strong scattering cross-section at the surface due to the surface atomic geometry.

#### 6.3 Surface Phonon Dispersion

The first direct measurements of the dispersion of surface phonons throughout the two-dimensional Brillouin zone were obtained using inelastic He atom scattering.\(^{(82)}\) However, improvements in EELS spectrometers soon permitted similar measurements based on inelastic electron scattering.\(^{(74)}\) Full measurements of phonon dispersion relations ($E(q_z)$ versus $q_z$) along high-symmetry directions of the two-dimensional Brillouin zone can be used to study surface interaction potentials by comparing the experimental phonon dispersion curves with those calculated using lattice dynamics methods.\(^{(83,84)}\) A typical EELS spectrum showing loss and gain peaks from phonons on Ni(100) is shown in Figure 3. It is now possible to calculate lattice dynamics based on first principles approaches. Thus, measurements of surface phonon energies throughout the two-dimensional Brillouin zone supported by analysis of the surface lattice dynamics offers important opportunities for improving understanding of surface phenomena associated with interaction potentials, i.e. surface relaxation and reconstruction as well as film nucleation and growth.

#### 6.4 Semiconductor Surfaces

EELS can be used as a probe of the transport properties of semiconductor surfaces.\(^{(13–15,85,86)}\) The Fermi energy in semiconducting materials lies in a gap in the electronic structure. At low temperatures and low beam energies,
the elastic peak width for semiconductors (and insulators) is very narrow due to the absence of very low-energy electronic excitations (no free carriers). An increase in temperature (or equivalently doping) leads to a finite and increasing free carrier concentration. This in turn leads to increased electron scattering and excitation of low-energy plasmons; surface energy loss mechanisms become possible and contribute to the elastic-peak width. The manifestation of the temperature-dependent loss mechanisms is a strong temperature dependence of the elastic-peak width. Theoretical models of quasielastic scattering\(^{4, 5, 46–48}\) permit calculation of bulk carrier density and estimates of other important parameters such as band gaps and effective masses of carriers. In the case of Si(111) \(7 \times 7\), analysis of the quasielastic peak has led to a model of the reconstructed surface in which two-dimensional metallic behavior is ascribed to the clean surface. The metallic character arises from surface states in the band gap. Adsorption of 1% of a monolayer of H on the Si(111) \(7 \times 7\) was found to quench the metallic surface properties effectively as evidenced by suppression of elastic-peak broadening. Corresponding studies of GaAs(100) surfaces have explored similar surface conductivity effects.\(^{48}\)

6.5 Ultrathin Metal Films

A thin metal film deposited on an insulating or semiconducting surface will behave as a two-dimensional conducting system. The same dielectric response formalisms developed to analyze quasielastic scattering in terms of surface conductivity apply to the thin film systems. EELS studies of ultrathin films deposited on semiconductor surfaces\(^{85, 86}\) have been interpreted within the dielectric models to yield the frequency-dependent film conductivity and used to characterize the effects of film microstructure on electron transport in the films.

6.6 High Critical Temperature Cuprate Superconductors

EELS has been used to explore electronic and vibrational properties of \(\text{YBa}_2\text{Cu}_3\text{O}_7\) and \(\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_8\) single crystals. Initial experiments\(^{87, 88}\) detected temperature-dependent loss features that were interpreted as resulting from high-conductivity regions of the surface, and attributed to the superconducting energy gap. Subsequent experiments\(^{89, 90}\) supported by a model\(^{90}\) for dipole inelastic electron scattering from a superlattice consisting of anisotropic-dielectric layers (modeling the cuprate materials) have shown that all loss features are nicely accounted for based on surface optical phonons. This application is a good example of the importance of using meaningful theoretical models to support the interpretation of EELS measurements, and an additional demonstration of the equivalence of dielectric response as measured independently by optical and inelastic electron scattering techniques.

6.7 Electronic Excitations at Surfaces/Surface Plasmons

Modern EELS instruments have recently been used to study collective surface electronic excitations (surface plasmons). Existing theoretical models\(^{91–93}\) suggest that knowledge of the surface–plasmon dispersion relations can lead to better understanding of intrinsic surface properties such as electron screening and the charge-density profile normal to the surface. The measurements of surface plasmon dispersion are similar to those used to determine surface–phonon dispersion. In the case of surface–plasmon dispersion measurements, it is no longer valid to assume that the electron energy loss \(\Delta E = E_i - E_s\) is much smaller than the incident energy \(E_i\), and an exact form of Equation (9) is required, Equation (10):

\[
\sqrt{\frac{2m}{h}} E_i \sin \theta_i - \left(1 - \frac{\Delta E}{E_0}\right)^{1/2} \sin \theta_s = \Delta k ||
\]

EELS experiments\(^{94}\) studying surface plasmons on K and Na confirmed theoretical predictions based on the jellium model of the electron gas: the energy of the surface plasmon at small values of \(k ||\) was found to be equal to \(w \approx w_p \sqrt{2}\) (where \(w_p = 4\pi n e^2/m\) the bulk plasmon frequency) and independent of the surface charge profile. Also, the dispersion at small \(q_s\) was found to be negative. Corresponding experiments on Ag\(^{95, 96}\) are beginning to clarify how surface plasmons are affected by more complex electronic structure.

7 APPLICATIONS TO CHEMISORBED ATOMS AND MOLECULES

Applications of EELS to surface chemical phenomena cover a very broad range of topics and the literature is extensive. This section highlights a few of the more important applications of EELS to the study of surface chemical phenomena by discussing selected “textbook” examples in sufficient detail to illustrate principal concepts.

7.1 Atomic Adsorbates

The simplest surface chemical systems involve dissociative chemisorption of diatomic molecules (or in some cases more complex gas phase species) that leave a single atomic species adsorbed at the surface. Many examples
of this type of system exist. Two systems will be discussed here: H on W(100)\(^{97-99}\) and O on Ni(100).\(^{100-103}\)

The saturated coverage of H on W(100) (β₁ phase) consists of H atoms bridge bonded to W surface atoms yielding two H atoms per surface unit cell. Saturated hydrogen coverage on W(100) stabilizes the surface W atoms into a p(1 × 1) bulk termination; i.e., the novel order–disorder surface reconstruction\(^{81}\) observed on clean W(100) below room temperature does not occur on the β₁ H/W(100) surface. A single vibrational mode \(v_1\) at 130 meV is measured by EELS under specular scattering conditions at low impact energies. The 130 meV (dipole) vibrational loss corresponds to the symmetric stretch \(^\text{130 meV}\) is measured by EELS under specular scattering condition in EELS spectra obtained for scattering parameters close to LEED beam emergence conditions. Isotope substitution confirms the H adsorbate origin of the loss \(^\text{80 meV, \text{130 meV}}\) to vibrations parallel to the surface: \(v_2\) and \(v_3\) are assigned to vibrational displacements perpendicular and parallel to the bridge axis respectively, and the \(2v_1\) mode is an overtone of the strong perpendicularly polarized mode. The energy and angular dependencies of these modes and similar results obtained for D₂ (isotope substitution yields the same modes shifted to lower frequencies by \(\sqrt{2}\) have provided important insight into scattering mechanisms.\(^{39,64}\) mode assignments (based on orientation and scattering angle dependencies of mode intensities) and selection rules.

EELS experiments carried out using scattering conditions under which LEED beams emerge from the crystal have yielded evidence of the surface resonance scattering mechanism.\(^{62,99}\) Rapid variations in inelastic scattering cross-sections as a function of incident energy, \(E_i\), or incident parallel wave vector, \(k_i\), are apparent in EELS spectra obtained for scattering parameters close to LEED beam emergence conditions. Isotope substitution confirms the H adsorbate origin of the loss peaks.

Detailed analysis of the EELS peaks of \(\beta_1\)H and \(\beta_1\)D on W(100) reveal that the vibrational loss energies are functions of momentum transfer \(q_i\) along high-symmetry directions of the two-dimensional Brillouin zone.\(^{99}\) Dispersion of the loss peaks as a function of \(q_i\) is a manifestation of a collective excitation (in this case an adsorbate phonon). When lateral interactions between chemisorbed H atoms on W(100) are taken into account, the degeneracy of the three vibrational modes associated with noninteracting bridge-bonded H is broken yielding a possible total of six phonon modes (two atoms per unit cell × three degrees of freedom per atom). A lattice dynamical analysis\(^{99}\) of two- and three-body interactions for \(\beta_1\)H on W(100) accounts for the experimentally observed phonon modes in terms of weak (1/10 of the H-W force) repulsive lateral forces between the chemisorbed H atoms.

Similar EELS experiments and lattice dynamical analysis of \(c(2 \times 2)\) and \(p(2 \times 2)\) O on Ni(100), and other ordered chemisorbed layers,\(^{101-103}\) have been carried out. These studies demonstrate the sensitivity of substrate and adsorbate phonon dispersion to overlayer structure (height of oxygen atoms over the substrate), as well as the technique of using lattice dynamical analysis of surface phonons to obtain adsorbate–adsorbate and adsorbate–substrate interaction potentials. Experimentally determined phonon dispersion curves interpreted within lattice dynamical models have been useful in exploring the types of interaction potential most suitable for analyzing surface phonon data (very good fits were obtained with nearest neighbor only interactions, and no angle-bending forces). The studies also suggest that various features in the dispersion curves can be interpreted in terms of several types of lateral interaction including short-range direct coupling between adsorbates, indirect coupling through the substrate, and longer range dipole–dipole coupling.\(^{104}\)

### 7.2 Underlayer Formation at Metal Surfaces

In selected metal adsorbate systems, dissociative chemisorption can be accompanied by adsorbate place exchange or diffusion perpendicular to the surface normal direction yielding adsorbate atoms in subsurface sites near the surface. Systems that exhibit this type of behavior include O/Al(111),\(^{105,106}\) H/Nb(100)\(^{107-109}\) and H/Ni(111).\(^{110}\) Underlayer modes can be probed via both dipole\(^{105}\) and impact\(^{110}\) scattering mechanisms. For dipole scattering by a dipole located below the surface, the important parameter is the strength of the screened dipole potential. Using the Thomas–Fermi model to characterize the screening length, by the Thomas–Fermi wave vector, \(k_{TF}\), the potential of a dipole located a distance \(d\) below the surface scales as \(\phi \sim 2 \exp(-k_{TF}d)\). For impact scattering, the important factor is the inelastic mean free path of the incident electron. The scattering intensity scales as \(I \sim \exp(-2d/E_i \cos\theta)\) where \(\xi_e(E_i)\) is the inelastic mean free path of incident electrons of energy \(E_i\).

Oxidation at the Al(111) surface is a complicated process involving the formation of a subsurface oxygen structure at the earliest stage of chemisorption. EELS studies\(^{105,106}\) of this system yielded the first definitive evidence suggesting that the initial stage of oxidation at Al(111) involved the simultaneous formation of chemisorbed surface and subsurface oxygen. Oxygen dose and substrate temperature-dependent studies of EELS peak intensities (see Figure 6) revealed a tendency of subsurface sites to become populated at the expense of surface sites at fixed oxygen dose, as well as the evolution of the loss spectra signature toward the spectra characteristic of Al₂O₃ as dose and temperature were
subsurface oxygen atoms. A surface structural model that included both surface and subsurface sites include new peaks in the off-specular scattering spectrum: the surface H yields peaks at 145 meV (symmetric stretch) and 118 meV (asymmetric stretch); the subsurface species produces a new peak at 145 meV (symmetric stretch) and 118 meV (asymmetric stretch). Manifestations of the subsurface sites by H atoms. Manifestations of the subsurface sites by H atoms. A suitably long exposure of Ni(111) to atomic H (dissociated by a 1800 K tungsten filament) results in the population of subsurface sites by H atoms. Manifestations of the subsurface adsorption sites include new peaks in the thermal desorption spectrum and a new peak in the off specular scattering spectrum: the surface H yields peaks at 145 meV (symmetric stretch) and 118 meV (asymmetric stretch); the subsurface species produces a new peak at 99 meV. Off-specular scattering studies of the 99 meV loss peak revealed that it is produced by impact scattering. Impact energy dependence of the same peak confirms that its intensity is compatible with an inelastic mean free path of $\xi_e \approx 2.05 \text{Å}$, corresponding to rapid decay of the electron penetration depth at the surface. In this case, dipole scattering is apparently very weak for the subsurface site, and the impact scattering vanishes in specular scattering based on a selection rule assuming a site of octahedral symmetry.

7.3 Molecular Adsorbates

EELS has been used extensively as an analytical tool to probe the adsorption and dissociation of molecules at metal(104,111,112) and semiconducting(113–117) surfaces. Extensions of these studies include investigations of surface-mediated chemical reactions, studies of model-supported catalysts, alkali metal promotion, and a broad range of technologically important surface processes.(4,5) As the size and complexity of molecules increases, the number of vibrational modes increases and an EELS spectra can become complex. Analysis of complex EELS spectra are facilitated by the broad range of source material that tabulates molecular vibrational spectra,(15–21) and the use of isotopic substitution techniques and angle dependencies which permit exploiting selection rules. In many cases, distinct groupings of frequencies associated with stable molecular fragments can be used to simplify mode assignments. For details, refer to sections of reviews(4,5) dealing with complex molecules, scientific papers by analytical chemists, and the books containing tabulations of vibrational frequencies.(15–21)

7.4 Technical Surfaces

While most applications of EELS techniques have focused on studies of electronic and vibrational excitations of well-characterized single crystal surfaces, some recent efforts have expanded applications to a class of surfaces that can be defined as technical surfaces (see Figure 7). The term technical surface is a descriptively appropriate term for surfaces such as supported catalysts (metal clusters on an oxide substrate), thin SiO2 insulators found in metal oxide semiconductor (MOS) technology, the surface of a Si wafer after a wet chemical step (HF dip cleaning) in a semiconductor Fab line, or a polymer surface. Several technical articles(118–121) and reviews(122,123) have addressed application of EELS to these types of surfaces. The same basic principles that govern scattering mechanisms and interpretation of loss peaks that apply to EELS studies of single crystal surfaces also apply to technical surfaces. However, at a practical level, there are significant differences: any surface involving an insulator is likely to exhibit effects associated with charging by the electron beam; diffuse elastic scattering will generally be much stronger (factor 10–100) due to the rougher nature of the surface; dipole scattering will generally be significantly reduced; and inhomogeneous broadening of loss
Charging is generally not a problem in ultrathin insulating layers and semiconductor surfaces, but in bulk insulators and thick insulating films, electron beam charging must be neutralized by a secondary electron gun flooding the sample (1 kV energy, 100 nA cm\(^{-2}\) beam current).\(^{118,119}\) The mechanism for surface charge elimination apparently involves the creation of a low-density surface plasma that conducts excess charge to an appropriate reference potential, the spectrometer ground.

EELS has been successfully applied to the analysis of surface chemistry involving a model supported catalyst.\(^{120}\) A thin film of alumina was grown by reactive Al deposition on a metal substrate in an oxygen atmosphere. The film was thin enough for tunneling or other mechanisms to prevent charging during EELS experiments. Vapor-deposited platinum (of the order of one monolayer effective coverage) produced Pt clusters ranging from 1.0–1.6 nm diameter due to the nonwetting properties of Pt on alumina. Loss features for \(\pi\) and di-\(\sigma\)-bonded ethylene species were observed after ethylene adsorption at 165 K (the dominant scattering mechanism was impact scattering and intensities were low), and upon warming the sample to 325 K, principal loss features corresponding to the formation of ethylidyne were clearly observed.

EELS has also recently been applied to the analysis of Si and SiO\(_2\) surfaces during wafer processing.\(^{119}\) Analysis of chemicals on the SiO\(_2\) surfaces required suppression of surface charging by using a secondary electron flood gun.

As a final example of the use of EELS in examining technical surfaces, recent work has developed useful applications to polymer surfaces.\(^{121,122}\) The ability of EELS to serve as an analytical probe of selected characteristics (surface uniformity or other quality control parameter) is already evident. Additional improvements should broaden applications to polymer and other technical surfaces.

### 8 COMPARISON WITH OTHER SPECTROSCOPIC METHODS

The EELS technique probes surface species and intrinsic surface properties by measuring energy loss of scattered electrons resulting from vibrational or electronic excitations. A broad range of surface-sensitive probes are available that can detect surface species, and several alternate spectroscopic techniques are available that are sensitive to vibrational and electronic excitations. In most research efforts, a single technique is not able to provide all of the required structural, compositional, chemical, vibrational or electronic information, and a combination of probes is usually incorporated into the instrumentation.

Surface vibrational excitations can be probed by IRAS, Raman scattering spectroscopy, and by neutral atomic beam scattering, usually HAS. The optical probes, IRAS and Raman scattering, achieve higher energy resolution (typically 0.1–0.5 meV) and offer the ability to probe surfaces under high ambient pressures. The sensitivity of the optical probes tends to be lower than EELS due to weaker coupling of photons to vibrational (and electronic) excitations, although the stability and intensity of synchrotron radiation and new laser technology applied
respectively to IRAS and Raman spectroscopy now permit studies at low surface concentrations.

IRAS probes vibrational modes having dynamic dipole moments perpendicular to the surface and can only detect surface phonons at $\Delta q = 0$; EELS can, in principle, detect vibrational modes of all polarizations, and can measure the energy loss and momentum transfer associated with scattering from phonons throughout the two-dimensional Brillouin zone. HAS achieves high-energy resolution (0.1–0.5 meV) and also exhibits high-surface sensitivity resulting from the surface scattering mechanism. The energy range of the incident beam is limited to relatively low values ~0.1 eV, therefore, atom beam scattering is best suited for studying low-energy surface phonons (below ~60 meV). A large fraction of our experimental knowledge of surface lattice dynamics has been obtained using He scattering.

Surface structure and chemical composition can be probed by EELS, and by other surface sensitive techniques. Vibrational excitations are sensitive to symmetry and local geometry, and, in many cases, the number and symmetry of vibrational excitations can yield information on the local environment of a chemisorbed atom. Other probes such as LEED, photoelectron diffraction (PED), and scanning tunneling microscopy (STM) offer more direct structurally sensitive means of determining atomic level geometry at surfaces.

AES and ESCA are highly sensitive and accurate probes of atomic species at surfaces. Both AES and ESCA are atomic probes, and rely on relative strengths of electron emission from atomic levels to infer chemical composition. Auger spectroscopy is unable to detect hydrogen. Other elements can generally be probed by AES at a detection limit of ~0.01 monolayer equivalent coverage. EELS has the advantage of probing energy losses that are characteristic of a molecule (a vibrational excitation) and therefore generally provides a better chemical probe of surface species.

An additional and very important complementary surface sensitive technique that is often used in conjunction with EELS is TDS. The technique involves measurement with a mass spectrometer of the molecular (and in rare cases atomic) species that are desorbed from a surface as the temperature of the crystal is ramped. The TDS technique can be extremely sensitive (individual ions, molecules or atoms can be detected) and can provide detailed information about desorbed species, and their surface binding energies.

In analytical electron microscopy (AEM), several imaging, diffraction and analytical modes are integrated in a design to provide analytical synergism having obvious advantages over any single instrument. The subject of AEM is to determine the morphology, crystallinity, defect structure, phase and elemental compositions and electronic properties of a material using the focused electron beam and signals generated in the course of its interaction with the specimen. The article considers history and stages of development of AEM, theoretical aspects of electron beam–solid interactions, instrumentation and methodology of particular techniques and image analysis, sample preparation and some typical applications. Various electron–specimen interactions generate a great deal of structural and analytical information in the form of emitted electrons and/or photons and internally produced signals, such as elastically and inelastically scattered electrons, Auger electrons (AE), X-rays and cathodoluminescence (CL), which can be analyzed in different operating modes. Imaging of transmitted solid materials is essentially due to elastic scattering (diffraction) of electrons by the periodic arrangement of atoms in crystals (diffraction contrast) and/or interference of several diffracted and transmitted beams (phase contrast). High-resolution imaging in the scanning transmission mode is also possible by using incoherently scattered electrons (Z-contrast). Inelastic interactions are forming the basis for all chemical analytical techniques (energy-dispersive (X-ray) spectroscopy (EDS) and wavelength-dispersive (X-ray) spectroscopy (WDS), electron energy-loss spectroscopy (EELS)/energy-filtering transmission electron microscopy (EFTEM), AE and CL spectroscopy). Basic data characterizing state-of-the-art modern AEM and current trends in its development are presented.

1 **INTRODUCTION**

1.1 Analytical Electron Microscopy: Subject, Advantages and Limitations

There are two main essentially different classes of electron microscopy (EM) techniques. In the first class, the electron probe is a stationary beam incident along a fixed direction. This incident beam can be either parallel [transmission electron microscopy (TEM), high-resolution transmission electron microscopy (HRTEM), high-voltage transmission electron microscopy (HVTEM),...
selected-area electron diffraction (SAED)] or convergent [convergent-beam electron diffraction (CBED), convergent-beam electron microscopy (CBEM)]. The resolution is determined by the quality of the imaging optics behind the specimen. Instruments implementing these techniques are conceptually related to classical light microscopes.

In the second class of methods, a fine electron probe is scanned across the specimen and transmitted electrons (TE) [scanning transmission electron microscopy (STEM)] or the desired excited signal such as secondary electrons (SE) or backscattered electrons (BSE) [scanning electron microscopy (SEM)], and/or AE [Auger electron spectroscopy (AES)/scanning Auger microscopy (SAM)] are selected, detected, amplified and used to modulate the intensity of another electron beam which is scanned synchronously with the first one over the screen of a TV monitor. The stationary beam methods are based on image formation processes whereas the scanning methods are essentially “mapping” techniques. Their resolution is mainly determined by the probe size, i.e. by the probe formation electron optics. The magnification is geometric, it is determined by the ratio of the areas scanned by the electron beam on the screen and synchronously by the electron probe on the specimen.

AEM is a logical extension of a concept referred to as an integrated modular EM system, which combines several electron imaging and diffraction modes and a number of analytical facilities. In this concept imaging modes [conventional transmission electron microscopy (CTEM), HRTEM, STEM, SEM, EFTEM], diffraction modes (SAED, CBED) and analytical modes [EDS and WDS, EELS and/or CL] are integrated in a design to provide analytical synergism having obvious advantages over any single instrument.

Moreover, the number of signals and contrast effects available in AEM may require the development of an optimum strategy for its application to the structural and analytical characterization of certain materials. This should take into account coordination of the methods being used, image processing, storage of data, separation and preparation techniques involved and mechanisms of the electron beam–specimen interactions and solid-state models of the material under study. The potential of AEM only became exploited with the development of nanochemistry and high nanotechnologies related particularly to cluster-matter such as cluster-produced thin films, nanocrystalline materials and cluster–matrix systems (metal–nonmetal systems, granular superconductors, cluster tunnel junctions, cermets).

The purpose of AEM is to determine both qualitatively and quantitatively the morphology, crystallinity, defect structure, phase and elemental compositions and electronic properties of a material at lateral spatial resolutions down to 0.5 nm within a single instrument using the focused electron beam and signals generated in the course of its interaction with the specimen. In principle, owing to the common origin of the interactions of fast electrons with a solid, all electron beam-based analytical techniques such as electron probe X-ray microanalysis (EPMA), analytical SEM and AES/SAM may be associated with AEM.

Since inelastic scattering of the incident electrons causes radiation damage, AEM methods, and EM in general, are destructive, although the extent of the damage is influenced by the electron dose needed to collect a useful signal, which in its turn depends on the instrumental performance. Moreover, TEM requires very thin specimens, which often implies cutting and thinning.

1.2 Short History and Stages of Development

Microanalysis by electrons and beam-generated X-rays and its basic concepts were first developed in the 1940–60s. Instruments for analytical SEM, EPXMA, TEM and STEM equipped with imaging filters, EDS and/or WDS and EELS were successfully utilized for the elemental and compositional characterization of advanced materials in a variety of fields of materials science. In the mid-1960s, when the advantage of using thin foils as specimens for X-ray analyses was recognized, Duncumb developed the first electron microscopy microanalyzer (EMMA), which comprised a 100-keV transmission electron microscope and wavelength-dispersive X-ray spectrometers. However, the efficiency of detection for WDS was low, and a higher beam current was required, which unfortunately increased the probe size to more than 100 nm. Fortunately, an EDS instrument was invented in the early 1970s and was fitted to an Auger electron microscope. It was placed within 1–2 cm of the probe and thus enabled one to measure a sufficiently large fraction of the X-ray flux produced by electron probes even smaller than 10 nm in diameter.

EELS records the energy distribution of beam electrons: TE after having interacted with a thin specimen without reflection or absorption. Hence interaction takes place inside the specimen, and information about its structure could be obtained by the use of an electrostatic or a magnetic electron spectrometer. The first low-loss electron energy-loss (EEL) spectrum of 5.3-keV electrons transmitted through a thin self-supported Al foil was recorded by Rutherford. Hillier and Baker reported inner-shell EEL spectra K-ionization edges of several elements and Fe L- and M-edges using the first electron microanalyzer, which could focus 25–75-keV electrons into a 20-nm probe used as microprobe or shadow microscope. A 180° magnetic spectrometer was used to record
energy losses of TE. A prism–mirror–prism energy filter incorporated into the column of a TEM instrument as proposed by Castaing and Henry\(^8\) was applied not only to acquire EEL spectra but also to display images and diffraction patterns of a specimen at a selected energy loss. An alternative method of energy filtering is the use of a STEM instrument equipped with an electrostatic energy analyzer.\(^9\) During the last three decades various electrostatic and magnetic electron analyzers and energy filters (Mollenstedt analyzer, Wien filter, omega filter, single-prism spectrometers, prism–mirror–prism filter, postcolumn quadrupole and sextupole lens spectrometers) have been developed.\(^{2,10,11}\)

Modern AEM systems are based on computer-controlled parallel electron energy-loss (PEEL) spectrometers and energy filters equipped with charge-coupled device (CCD) cameras in a combination with solid-state Si/Li and intrinsic Ge (EDS) and crystal (WDS) detectors as well as scanning attachments fitted with multidetector systems for imaging in bright field (BF) and dark field (DF) TEM/STEM and diffraction (SAED, CBED) modes, in SE/BSE/SEM, and in annular dark-field (ADF) STEM modes.

### 2 THEORY AND INSTRUMENTATION

#### 2.1 Electron–Solid Interactions

AEM is based on the effects of elastic and inelastic scattering of an accelerated electron beam upon interaction with atoms and electrons of the material to be examined.\(^{12}\)

The final signals used for image formation and for analyses are normally not the result of single scattering but of some electron diffusion caused by the gradual loss of the electron energy and by some lateral spreading mainly due to multiple elastic large-angle scattering. Figure 1 describes schematically the most important interaction processes and signals detected in different operating modes of AEM and their information volumes (inset). The complete energy spectrum comprises primary electrons (PE) with energy \(E_0\), and emitted electrons, ions, heat, quanta and internally generated signals such as the following: TE; wide-angle and narrow-angle elastically scattered and/or diffracted electrons (DE); BSE; SE; inelastically scattered electrons with loss of energy; sample current (SC) or absorbed electrons; AE; hard and soft characteristic and continuous X-ray photons; CL; and electron plasmons (EP) and lattice phonons (LP).

Usually only a comparatively small fraction of the characteristic X-rays isotropically emitted from the specimen is detected because of the small solid angle of collection (\(10^{-3} \text{–} 10^{-1}\) sr). Moreover, inner-shell ionizations result in the emission not only of X-rays but also of AE and the X-ray fluorescence yield decreases with decreasing sample atomic number \(Z\), even below 1% for light elements. A large fraction of about 10–70% of the inner-shell ionization processes are associated with inelastically scattered electrons concentrated in small scattering angles which also pass through the objective diaphragm. Atomic electrons can be excited from an inner shell to unoccupied energy states above the Fermi level, resulting in a characteristic edge in the EEL spectrum. Complementary to X-ray spectroscopy, in specimens with thickness of about or smaller than the mean free electron path, the well defined ionization edges for elements with atomic number \(2 \leq Z \leq 92\) can be analyzed.\(^{2,13}\)

The plasmons and inelastic intra- and interband excitations of the outer shell electrons near the Fermi level that normally can be observed with energy losses \(\Delta E\) smaller than 50 eV are influenced by chemical bonds and the electronic band structure by analogy with optical excitations. In semiconductors the electron impact results in the generation of electron–hole pairs and causes an electron beam-induced current (EBIC). Electron–hole pairs can recombine with emission of
luminescent photons, either in the ultraviolet, visible or infrared (IR) regions or by nonradiative LP. Some fraction of the $E_0$ that is lost in the course of a cascade of inelastic scattering processes is converted into phonons and/or heat and causes radiolysis, thermal damage, bond rupture and loss of mass and crystallinity by the sputtering of specimen matter.

Ionization of an inner electron shell by the inelastic impact results in a hole, which can be filled by an electron from a higher state. The energy difference can then be emitted either as a characteristic X-ray quantum or as an AE. Hence the X-ray spectrum represents the transition between two energy levels, and the generated intensities are the product of the state density and the transition rate governed by the selection rules.

Since the actual mechanisms of electron–solid interactions are complicated, estimations of the information volume of generated signals based on Monte Carlo simulations (Figure 2a–c) are of importance, in particular for understanding relationships between scattered electrons and produced X-rays. The consequence of the gradual decrease of the electron energy is that the electrons have a finite depth range of the order of several nanometers up to tens of micrometers depending on the $E_0$ value and the thickness and density of the specimen. The depth and the lateral extent of the information volume governing the resolution of the corresponding operating modes contribute to each of the possible signals, decreasing considerably with a decrease in specimen thickness and an increase in its density. Hence the various electron–specimen interactions can generate a great deal of structural and analytical information in the form of emitted electrons and/or photons and internally produced signals. Inelastic interactions form the basis for all chemical analytical techniques.

### 2.2 Diffraction by Crystals

#### 2.2.1 Diffraction Effects; General Considerations

The complete characterization of solid compounds, especially of crystalline matter, requires, apart from a knowledge of the chemical composition, also a description of the crystallographic features, i.e., lattice parameters, space group, and crystal structures. Moreover, a number of technologically important properties are “structure” sensitive, i.e., are influenced by the state of perfection and purity of the crystals and may depend on the microtexture.

Images of solid materials produced in TEM are essentially due to elastic scattering, i.e., to diffraction of electrons by the periodic arrangement of atoms in crystals (diffraction contrast). Not only is diffraction responsible for the formation of the images, but also the diffraction pattern allows the determination of the crystallographic features. In the same instrument it is possible easily

**Figure 2** Monte Carlo simulations of a lateral electron distribution (blue) and Si Kα X-ray emission (red) in a multilayer composite film at (a) 8, (b) 100 and (c) 300 keV, 32000 trajectories, 40° tilt. Histogram of normalized yield of Si Kα emission, $f(rz)$, is plotted on the right side of the graphs starting at the crystal surface; the length of bars shows the relative value of $f(rz)$ at that depth. 1, Al, 300 nm; 2, SiO₂, 250 nm; 3, Si₃N₄, 200 nm; 4, WSi₂, 50 nm; 5, SiO₂, 100 nm. Calculations indicate a possibility of analyzing the top layer by reducing the accelerating voltage to <8 kV and an improvement in lateral resolution and sensitivity at 300 kV compared with 100 kV.
to obtain the electron diffraction (ED) pattern of a small crystal fragment and the image of the same small area without changing the relative orientation of the specimen and the beam. The knowledge of the relative orientation of image and diffraction pattern is essential for a detailed interpretation of the image.

2.2.2 Scattering by Atoms
The elastic scattering of electrons by atoms is governed by Coulomb interaction; it contains two contributions of opposite sign. The first is due to the positively charged nucleus whereas the second is due to the negatively charged electron cloud. It is described by the atomic scattering factor according to Equation (1):

$$f_x(\theta) = \frac{m e^2 \lambda}{2 h^2} Z \frac{f_x(\theta)}{\sin \theta}$$

where $Z$ is the atomic number, $f_x(\theta)$ is the scattering factor for X-rays, $m$ is the electron mass, $e$ is the electron charge, $\lambda$ is the de Broglie wavelength of the electron and $h$ is Planck’s constant. The interaction with atoms is stronger for electrons than for X-rays. As a result, scattering processes in crystals are best described by dynamic diffraction theory, which takes multiple scattering events into account. However, for many applications kinematic diffraction theory is a sufficiently good approximation.

2.2.3 Geometry of Diffraction by Periodic Structures
The direct lattice of a crystal has node points at positions $r_L$ (Equation 2):

$$r_L = l_1a_1 + l_2a_2 + l_3a_3$$

where $a_1$, $a_2$, $a_3$ are the basic lattice vectors and $l_1$, $l_2$, $l_3$ are integers. Reciprocal space, also called diffraction space, consists of reciprocal lattice nodes at positions (Equation 3):

$$b_H = l_1b_1 + l_2b_2 + l_3b_3$$

where the $b_i$ are the basic vectors of the reciprocal lattice defined by the relations $a_i b_j = \delta_{ij}$ and $H = (h_1, h_2, h_3)$ are integers called Miller indices. The interplanar spacing of lattice planes with Miller indices $H$ is $d_H = 1/|b_H|$.

2.2.3.1 Bragg’s Law
The condition for diffraction to occur can be expressed either in direct space by Bragg’s law or in reciprocal space by Ewald’s condition. Bragg’s law (Figure 3a\(^{19}\)) (Equation 4):

$$2d_H \sin \theta_H = n\lambda$$

($n = \text{integer}$) states that a strongly diffracted beam will form whenever the incident beam with wavelength $\lambda$ encloses a Bragg angle $\theta_H$ with the set of lattice planes with Miller indices $H$. It expresses the condition that the path difference $\Delta$ between beams “reflected” by successive lattice planes with spacing $d_H$ should be an integer number $n$ of electron wavelengths $\lambda$. In ED due to the small wavelength of the electrons, Bragg angles $\theta_n$ are only a few degrees at most.

2.2.3.2 Ewald Construction
The Ewald condition (Figure 3b) for strong diffraction by the set of planes with indices $H$ can be formulated as Equation (5):

$$k_x = k_0 + g$$

where $g = b_H, k_0$ is the wavevector of the scattered wave and $k_0$ that of the incident wave and $g$ is the diffraction vector. The physical content of the Ewald condition is the same as that of Bragg’s law since $|k_g| = |k_0| = 1/\lambda$ and $d_H = 1/|b_H|$. The Ewald condition expresses the conservation, on scattering, of energy and linear momentum of the incident electrons. It leads to a simple geometric construction of the scattered beam direction. Consider a sphere with radius $1/\lambda$ and with its center $C$ in $-k_0$ with respect to the origin $O$ of the reciprocal lattice (Figure 3b). Diffraction will occur when the sphere touches a reciprocal lattice node. The wavevector of the scattered wave $k_g$ is then obtained by joining the center of Ewald’s sphere $C$ with the excited reciprocal lattice node.

2.2.3.3 Thin Foil Effects
The specimens used in TEM have to be thin (of the order of 100 nm). The actual useful thickness depends on the accelerating voltage of the electrons as well as on the material. For thin specimens, the diffraction conditions are relaxed (Figure 4b). Even if the Ewald condition is not exactly satisfied, diffraction occurs. In terms of reciprocal space, the nodes become “rods” (relrods) having a weight profile.
Figure 4 Diffraction condition in thin foil. (a) The Ewald condition is exactly fulfilled for the reciprocal lattice node \( \mathbf{H} \). (b) The Ewald condition is only approximately satisfied; the node \( \mathbf{H} \) is missed by the excitation error \( s \) along the “relrod”.

Figure 5 (a) Weight profile of the amplitude along the “relrod” as a function of the excitation error \( s \) \( (z_0 = \text{foil thickness}) \). (b) Rocking curve according to the kinematic diffraction theory: scattered intensity \( I_s \) as a function of the excitation error \( s \) \( (z_0 = \text{foil thickness}) \).

Figure 6 Propagation of electrons along a column. (Left) According to the kinematic theory: only single scattering events occur. (Right) According to the dynamic theory: multiple scattering events occur.

Figure 7 BF diffraction contrast image of a stainless-steel foil containing various types of defects: dislocations (D), twin boundaries (T), stacking faults (S) and grain boundaries (K).

2.2.4 Kinematic Diffraction Theory

According to the kinematic theory, the scattered intensity \( I(s, z_0) \) for a foil with a thickness \( z_0 \) is given by Equation (6):

\[
I(s, z_0) = F_H^2 \frac{\sin^2 \pi s H z_0}{(\pi s H z_0)^2}
\]

where \( F_H \) is the structure factor of reflection \( H \) for which the corresponding excitation error is \( s_H \). This relation describes the “rocking curve” shown in Figure 5(b).
The loci corresponding to $s_{\mathbf{n}} = \text{constant}$ or $z_0 = \text{constant}$ values corresponding to maxima of $I(s, z_0)$ are imaged as bright fringes.

The electron wavevector $[k_0 \sim (1/0.004) \text{ nm}^{-1}$ at 100 kV] is of the order of 50 times larger than the mesh size of the reciprocal lattice ($\sim 1/0.1 \text{ nm}^{-1}$); the Ewald sphere can thus be approximated by a plane perpendicular to $k_0$ and the geometry of the ED is thus given by a planar section of reciprocal space. Usually the diffraction pattern will thus exhibit a planar lattice of spots (Figure 8a and b).

By tilting the specimen, an orientation can be achieved whereby one diffracted beam is much more intense than all others and comparable in intensity to that of the transmitted beam. Such a “two-beam situation” is desirable for a detailed interpretation of defect images since then the image producing the diffraction vector is well defined.

2.2.5 Dynamic Theory

In a two-beam situation, the diffracted and the incident beam play equivalent roles in the interior of the crystal, the diffracted beam being incident under the Bragg angle for the same set of planes as the incident beam. The dynamic interplay of incident and diffracted beams leads to a rocking curve for the scattered beam given by

\[ I_s = \frac{1}{(\sigma_{\mathbf{n}})^2} \sin^2 \pi \sigma_{\mathbf{n}} z \]  

Equation (7):

where $1/\sigma_{\mathbf{n}} = \mathbf{n}_t/(1 + s^2 \mathbf{n}_t^2)^{1/2}$, $\mathbf{n}_t$ being the “extinction distance”, which is inversely related to the structure factor $F_{\mathbf{n}}$; it is a measure for the strength of the reflection $\mathbf{H}$; a long $\mathbf{n}_t$ corresponds to a weak reflection; $z$ is the level behind the entrance face of the foil. The rocking curve of the transmitted beam is then $I_T = 1 - I_S$, if absorption is neglected. For $\mathbf{n}_t = 0$, i.e. for the exact Bragg condition, $I_S$ and $I_T$ vary periodically in depth $(z)$ with a period $\mathbf{n}_t$, $I_S$ and $I_T$ being in antiphase. This periodic character is attenuated by absorption (Figure 9).

2.2.6 Diffraction Contrast Images

Diffraction contrast images made under two-beam conditions are maps of the intensity distribution in a magnified diffraction spot: either the direct spot (BF image) or the diffracted beam (DF image). They reveal deviations from the perfectly periodic structure of the crystalline foil but they cannot provide information on the periodic structure.

Diffraction contrast arises because the intensity emerging from a column depends in general on its position. In a perfect undeformed foil of constant thickness, $s$ is constant along a column and the same for all columns. The thickness and the $s$ value determine the emerging uniform intensity, as given by the rocking curve. If the foil has constant thickness, but is bent, the image will exhibit bright contours corresponding to loci of constant $s$, so-called “bent contours”. If, on the other hand, the foil is undeformed but has a wedge shape, the image will consist of loci of constant thickness called “thickness or wedge

---

**Figure 8** Formation of the ED pattern. Each diffracted beam corresponds to an intersection point of the “relrods” in reciprocal space with Ewald’s sphere. In fact Ewald’s sphere is well approximated by a plane normal to $k_0$.

**Figure 9** Rocking curves according to the dynamic diffraction theory taking absorption into account: $I_T$ (curve a) and $I_s$ (curve b) as a function of $s\mathbf{n}_t$ ($\mathbf{n}_t = \text{excitation error of reflection } \mathbf{H}$; $\mathbf{n}_t = \text{extinction distance of reflection } \mathbf{H}$).
fringes”. Often, a foil will exhibit both types of contours simultaneously. They should be distinguished from defect images.

2.2.7 Defects Images and Their Interpretation

A dislocation line produces a line of contrast because in the vicinity of the dislocation the lattice planes change in orientation as a consequence of the associated strain field (Figure 10). On one side of the dislocation E a given set of lattice planes is inclined in one sense, whereas it is inclined in the opposite sense on the other side. On one side (E₁) of the dislocation the Bragg condition may thus be better satisfied than in the perfect part, whereas on the other side (E₂) the Bragg condition is then less well satisfied than in the perfect part (Figure 10). Along the columns on one side of the dislocation more intensity will then be diffracted than in the perfect part; the reverse is true on the other side of the dislocation. Hence, on one side of the dislocation a bright line is produced in a DF image, whereas on the other side a dark line is produced. The image is thus one-sided and the line image does not coincide exactly with the position of the dislocation line. Diffraction by lattice planes, which are not deformed by the presence of the dislocation, does not produce an image. A network of dislocations in graphite in which one set of dislocation segments remains invisible is shown in Figure 11(a) and (b).

A stacking fault parallel to the foil plane changes the intensity emerging from a column intersecting the fault plane. This intensity therefore depends on the level at which the fault occurs in the column. This intensity change results from the phase change of the diffracted electron wave caused by the parallel relative shift of the crystal structures above and below the fault plane. Inclined stacking faults are imaged as fringe patterns in the projected area of the fault plane (Figure 12a and b). The fringes are parallel to the intersection line of the fault plane and the foil surface; they result from the fact that the relative shift of the two crystal parts, separated by the fault plane, occurs at a varying level along the fault plane. The depth period of the fringes is equal to the “extinction distance”.

2.2.8 Lattice Fringes

Instead of providing an image by selecting a single beam, one can select both beams in a two-beam orientation (or more) by means of a large enough aperture. The interference of the beams produces a set of sinusoidal fringes with a spacing \( d_H = 1/|g| \) equal to the interplanar spacing corresponding to the selected diffraction vector \( g \), the direction of the fringes being perpendicular to \( g \). An intuitive, purely geometric model allows one to understand the formation of the lattice fringes. In the foil F represented in Figure 13(a) and (b), the set of indicated lattice planes with diffraction vector \( g \) has an interplanar spacing of \( d_H = 1/|g| \). The incident beam I satisfies the Bragg condition for diffraction by this set of

Figure 10 Formation of diffraction contrast image at an edge dislocation E. Left (at E₁) and right (at E₂) of the dislocation the considered lattice planes are inclined in opposite directions: the intensity distributions in the transmitted beam (I₁) and in the scattered beam (I₂). The resulting image profiles are denoted BF and DF, respectively. The two beam diffraction conditions are also represented in reciprocal space.

Figure 11 Network of dislocations in graphite as imaged in diffraction contrast. (a) All dislocations exhibit line contrast; (b) one family of dislocations is out of contrast.
planes, i.e. $s = 0$. The transmitted beam is $T$ and the Bragg scattered beam is $S$; they are assumed to represent plane waves with wavelength $\lambda$, which are perpendicular to the corresponding beams; they have maximum elongation along the heavy lines shown in Figure 13(a) and (b). The plane waves interfere behind the foil and intensity maxima will occur along the straight lines where the planes of maximum elongation of $T$ and $S$ intersect. The maxima are thus located along the straight lines seen end-on as black dots in Figure 13(a) and (b). As both waves propagate with the same speed, these lines of maxima move along planes $P_1$, $P_2$, $P_3$ with spacing $\Delta$, parallel to the considered lattice planes. Simple geometric considerations show that $d_H = \Delta$. The planes of maximum intensity form a stationary pattern and can thus be observed behind the exit plane of the foil. This pattern is an “image” of the lattice planes. The localization of the fringes (the image) relative to the lattice planes (the object) depends in reality on the diffraction conditions (in particular on $s$), but this has no practical significance in this simple case.

If we include next to the beam with diffraction vector $g$ also the diffracted beam with diffraction vector $2g$, the resulting interference pattern will also include parallel fringes with a spacing $1/2|g| = 0.5d$, i.e. features within the basic period $d$ are now imaged. As higher order reflections $ng$ are included in the interference pattern, the resulting fringe pattern will contain contributions (i.e. Fourier components) with period $d/n$ consisting of fringes perpendicular to $ng$. The higher the order of the included reflections, the finer is the detail that can be imaged, provided that the resolution of the microscope is able to resolve these fine details. In practice, the lattice resolution of present-day HRTEM is routinely limited to 0.16 nm and exceptionally to 0.1 nm.

2.2.9 High-resolution Images

2.2.9.1 Fourier Approach If one selects a two-dimensional array of spots centered on the direct beam, each pair of spots determines a diffraction vector $\hat{g}$, which will lead on interference to a set of parallel lattice fringes perpendicular to this vector (Figure 14a...
Figure 14 Formation of two-dimensional high-resolution image by the interference between the direct beam O and four diffracted beams (A, B, C, D). Each pair of beams produces a Fourier component with a wavevector given by the line segment connecting the two diffraction spots. Part (a) illustrates the superposition of the different Fourier components with wavevector \( \mathbf{g} \) giving rise to maxima in brightness, where the maxima of the different Fourier waves overlap.

and b). According to this model, the image will be formed by the superposition of all Fourier components with wavevectors corresponding to the diffraction spots admitted through the selector aperture. Unfortunately, the limited resolution due to the lens aberrations restricts the useful diffraction vectors \( \mathbf{g} \) and hence limits the detail achievable. This is due to the fact that beams enclosing increasing angles with the optical axis become increasingly out of phase with the paraxial beams and moreover become increasingly damped.

2.2.9.2 Channeling Approach  An alternative intuitive model emphasizes the fact that one images in reality atom columns parallel to the incident beam rather than single atoms. It considers the propagation (channeling) of electrons in the cylindrically symmetric electrostatic potential well due to the linear strings of atoms forming the columns (Figure 15). On propagating along such a column, the electron wavefunction is centered on the column and oscillates periodically in lateral extent and in intensity with a characteristic depth period \( \Delta_A \) (or \( \Delta_B \)) (comparable to the extinction distance in dynamic diffraction theory). This period is the shorter the larger the average \( Z \) value of the atoms in the string; it varies in length in the range from 4 to 20 nm. Depending on the foil thickness, columns may thus exhibit either a maximum or a minimum in brightness at the level of the exit surface. At a given thickness, columns having a different composition will in general produce dot images of a different brightness (Figure 16). However, whether a bright or a dark dot will be produced in the final image depends not only on the foil thickness, but also on the imaging conditions, i.e. whether the microscope is either over- or underfocused. Images are mostly taken under somewhat underfocused conditions (which produces the best contrast), optimizing in this way the window in the image transfer function\(^{20,21}\) (Figure 17a and b).
ELECTRON MICROSCOPY AND SCANNING MICROANALYSIS

The bright dots reveal the heavy atom columns as projected along two different zones. Simulated images are reproduced as insets. The projected unit cell is outlined (Courtesy of Professor G. Van Tendeloo). The images were made at optimum defocus. The two images refer to different specimens, with comparable thickness.

2.2.10 Image Interpretation

2.2.10.1 Trial and Error

Digital simulation programs for HRTEM are usually based on the Fourier approach.\(^{(19,22)}\) They allow one to compute the image of a given structure projected along a given zone axis as a function of the foil thickness and of the imaging conditions (defocus, ...) for a microscope with known characteristics (spherical aberration coefficient, accelerating voltage, beam convergence) (Figure 17a and b).

Identification of a structure or of a defect in a structure, proceeds by “trial and error”. A model is proposed and a matrix of images, varying the two main independent variables (foil thickness and defocus), is computed (Figure 17a and b). These theoretical images are then compared with the observed images at the different thicknesses along a wedge-shaped part of the foil. A solution is considered acceptable when the correspondence between observed and computed images is judged visually to be “good enough” for all available thicknesses at a constant defocus. This comparison allows one at the same time to estimate the foil thickness and the defocus; these quantities are usually not known a priori. Numerical criteria to quantify the “goodness of fit” have been proposed\(^{(21)}\) but have seldom been applied as yet. In recent developments, high-resolution images have been used to determine the chemical composition along individual columns in rather special circumstances such as along the interfaces in synthetic layer structures of semiconductors grown by molecular beam epitaxy. The composition profile across an interface can be obtained at an atomic scale. The application of these methods requires a certain amount of a priori knowledge concerning the structure.

2.2.10.2 Direct Retrieval

Recently, “direct retrieval” methods have been developed which use as the input a series of images taken at closely spaced defocus values (focus variation method).\(^{(19,20)}\) Knowing the microscope parameters describing the transfer function and its inverse, the projected wavefunction at the exit plane of the foil can be reconstructed. From this, the projected structure (the object) can be retrieved using an analytical formulation of the channeling model. Knowing the projected structure along more than one zone axis allows one to reconstruct the three-dimensional structure. Less a priori knowledge is required than for the methods based on “trial and error”.

2.2.11 High-resolution Defect Images

From high-resolution images with well-resolved atom columns, the presence of translation interfaces, such as stacking faults and out-of-phase boundaries, can be deduced directly from the relative shift of the column configurations in the two crystal parts. Only the component of the displacement vector perpendicular to the incident beam direction is obtained in this way. Since the lattice of the structure is represented directly by the dot configuration, also the orientation domain microstructure and its interfaces, for instance twins, can be imaged directly. The core configuration of dislocation lines parallel to the viewing direction can be imaged directly (Figure 18).

2.2.12 Selected-area Electron Diffraction

ED methods (SAED, CBED) are a useful complement to X-ray diffraction, especially when the material is available only as small microcrystals. Then only powder diffractometry can be applied when using X-rays. However, even fine powders usually contain single crystals of a sufficient size to produce a single-crystal ED pattern, and hence to allow the approximate (but unambiguous) determination of the lattice parameters. These approximate lattice parameters then in turn allow unambiguous indexing of the powder diffraction pattern and subsequently make possible a precise lattice parameter measurement. In addition, ED patterns often exhibit weak reflections due to superstructures, which are not visible in X-ray powder diffraction.

The spatial geometry of diffuse scattering can be reconstructed more easily from ED patterns than from
Figure 18 Core configuration of an edge dislocation in germanium as revealed by HRTEM. A Burgers circuit surrounds the dislocation.

X-ray diffraction patterns since ED patterns are planar sections of reciprocal space, which is not the case for X-rays.

2.2.13 Convergent-beam Electron Diffraction

In most commercial microscopes, it is possible to produce a “stationary” convergent incident beam rather than a parallel beam, by means of the condenser lens system. The electron beams are then incident along directions either within a cone of revolution or confined to a conical surface (hollow cone method), with a semiapex angle within the range 2–10 mrad. The apex of the cone is mostly situated close to the sample plane. The CBED pattern now consists of circular disks of which the size is proportional to the semiapex angle; they are centered on the positions of the Bragg spots that would be produced if the incident beams were parallel to the cone axis. If the semiapex angle is small enough, these disks do not overlap, but if the semiapex angle exceeds the Bragg angle of the lowest order reflections, these disks overlap and interference occurs between the electron waves in the overlap parts of adjacent disks. For a perfectly flat foil of constant thickness, the intensity distribution within well-separated disks images in a sense the rocking curve, associated with the corresponding Bragg spot. The interference between different, partly overlapping disks gives rise to complicated two-dimensional fringe patterns, which nevertheless still reflect the symmetry along the zone axis and are representative of the point group and of the space group of the crystalline sample, provided that the selected area is free from defects. A major application of CBED is the determination of crystal symmetry and of the strains in crystals, but also defects can be characterized using DF images and local strain patterns can be revealed. From intensity oscillations in the rocking curve obtained from DF images in a known disk, the foil thickness can be deduced with good accuracy.\(^{(19)}\)

2.2.14 Z-contrast Images

The commonly used imaging modes (CTEM, HRTEM), being based on interference and diffraction, rely strongly on coherently scattered electrons. However, simultaneously with the coherent scattering, incoherently scattered electrons also are produced by thermal diffuse scattering and in particular by Rutherford scattering. In the STEM mode these incoherently scattered electrons can be used to image atom columns, provided that the proper electron optics are available.\(^{(23)}\) A fine electron probe is obtained by focusing the incident convergent electron beam in the sample and scanning over the foil. Thereby, a significant fraction of the incoherently scattered electrons emerging from the sample at relatively large scattering angles is captured in an annular aperture and detected.

In the case of incoherent imaging conditions, the contrast transfer function is a monotonously decreasing function of the spatial frequency, whereas under coherent imaging conditions it is a rapidly oscillating function. This has important consequences. In the coherent case the brightness of a dot imaging a given atom column may change from bright to dark and vice versa as a function of defocus. In contrast, in the incoherent case, the relative brightness of a dot remains consistently the same, independent of defocus, i.e. there is no contrast reversal. Moreover, the dot brightness increases monotonously with increasing average \(Z\) value of the atoms in the column as a consequence of the contribution of the Rutherford scattering to the incoherently scattered electrons. Incoherent images can therefore be interpreted on an intuitive basis even for relatively large thickness. It can be shown that structure retrieval is in principle possible and simpler than in the case of coherent imaging.\(^{(19)}\) The method is therefore well suited to the study of geometric defects in crystals.

2.3 Inelastic Scattering Processes

Part of the electron kinetic energy is converted in the course of inelastic scattering due to the following atom–electron excitations:\(^{(12)}\)

1. Phonon excitations in solids \((0.02 \text{ eV} \leq E \leq 1 \text{ eV})\) normally superimposed with the beam energy spreading.
2. Volume and surface plasmon losses \((0 \text{ eV} \leq E \leq 50 \text{ eV})\) due to longitudinal oscillations of the plasma of valence and/or conduction electrons. The plasmon
energy loss, $E_p$, is expressed according to Equation (8):

$$E_p = hw_p = \frac{ne^2}{(\varepsilon_0 m)}$$

where $w_p = \frac{ne^2}{(\varepsilon_0 m)}$ is the plasma resonance frequency, $n$ is the electron density, $e$ is the electron charge, $\varepsilon_0$ is the permittivity of vacuum and $m$ is the electron mass. The low-loss region may also contain losses from the excitations of intra- and interband transitions and of Cerenkov radiation, sometimes overlapped by low-energy ionization edges of outer shells.

3. Quasi-free single-electron excitations (Compton scattering) due to an electron–electron collision, when the transferred energy is larger than the binding energy of excited electrons.

4. Inner-shell ionizations of electrons to a free state or to the continuum Fermi level resulting in the appearance of an elemental edge at $E = E_f$ followed by an intensity decrease in a long tail for $E > E_f$. The edge profiles (particularly for L- and M-edges) may often exhibit delayed maxima and narrow “white” lines. An energy-loss near-edge structure (ELNES), which is dependent on the local bonding and coordination of atoms, can be detected up to 50–60 eV beyond the ionization edge. An extended energy-loss fine structure (EXELFS) covering several hundred electron-volts beyond the edge may be observed owing to interference between the outgoing spherical ejected electron wave and reflected electron waves backscattered from neighboring atoms, thus giving information about interatomic distances.

2.4 Auger Electrons

AE emerge from a solid sample as a consequence of nonradiative rearrangement of the electrons in atoms in which a core hole has been created by the exciting radiation. For an Auger transition involving, for instance, the $j$, $k$ and $l$ levels, an electron leaves the solid with a certain kinetic energy, the atom being left behind in a doubly ionized state (Equation 9):\(^{(24)}\)

$$E_{\text{kin}}(jkl; X) = E_b(j) - E_b(k) - E_b(l) - F(kl; X) + R_e$$

where $X$ is the multiplet state resulting from the coupling of the two holes $k$ and $l$ in the final state, $E_b(j)$, $E_b(k)$ and $E_b(l)$ are corresponding ground-state one-electron binding energies, which take into account initial chemical shifts and one-hole relaxation phenomena, $F$ is the two-electron term and $R$ is a supplementary cross-relaxation energy containing both an atomic and extra-atomic contribution.

Since the primary energy of the exciting electrons in AES is normally in the range 3–10 keV, only K-shell core holes of the light elements can be created, giving rise to the K-series Auger lines. For medium and heavy elements one excites the L- and M-series Auger lines. The observed AE kinetic energies are usually situated in the range 0–2 keV, limiting the information depth. Electrons must escape from the sample surface without suffering inelastic collisions in order to be identified, and therefore the escape depth is limited to a few atomic layers only. Depending on the chemical environment of the ionized atom, shifts in the positions of AE peaks are observed. The shape of an AE line also strongly depends on the chemical environment. Both effects are important for chemical composition imaging.

2.5 X-rays

The X-ray emission spectra, shown in Figure 19(a–d) for a high-temperature superconductor YBa$_2$Cu$_3$O$_{7-x}$ ceramic, consist of a background (continuum X-rays, bremsstrahlung) which extends up to the energy of the incident beam, together with superimposed discrete characteristic lines of Cu (Cu K- and L-series), Y (Y K- and L-series), Ba (Ba L-series) and O (O K-series). Wavelength-dispersive X-ray spectra (b–d) demonstrate clearly much better resolution than energy-dispersive X-ray spectrum (a). The relationship between the energy of characteristic X-ray emission lines and the atomic number of the element of interest is described by Moseley’s law (Equation 10):

$$E = A(Z - 1)^2$$

where $A$ is constant within the K-, L- and M-series and $Z$ is the target atomic number. When an inner shell electron is ejected from the atom, the latter becomes ionized and goes to a higher energy state. An electron from one of the outer levels must fill the hole vacancy formed in this way. Electron transitions are regulated by the selection rule in which $\Delta n \neq 1$, $|\Delta l| = 1$, $|\Delta j| = 0$, where $n$, $l$ and $j$ denote principal quantum number, azimuthal quantum number and inner quantum number, respectively. An X-ray quantum can be emitted with a discrete energy corresponding to the difference in energy between the levels involved. Major X-ray emission lines together with their designation are shown in Figure 20. Actually, transitions which do not satisfy the selection rules, so-called “forbidden” transitions, can also occur and do produce some emission lines, but their intensities are usually low. Bonding also affects inner shell electrons owing to the change in the surrounding charge distribution. However, the range of characteristic lines,
which allow chemical effects to be observed, is fairly limited. This is because the spectrum does not always reflect changes in electron states: there are no changes in X-ray spectra if chemical effects on two different energy levels are the same.

The intensity of the total X-ray emission originating from depth $z$ (Figure 21) below the surface of a specimen with density $\rho$ including any fluorescence contribution may be expressed\(^{4}\) by Equation (11):

$$I = \phi(\Delta \rho z) \int_0^\infty \phi(\rho z) \exp(-\chi \rho z) d\rho z f(1 + \gamma + \delta)$$

(11)

where $\phi(\Delta \rho z)$ is the emission from an isolated thin film of mass thickness $\Delta \rho z$, $\chi = (\mu/\rho) \cosec \psi$, $\rho z$ is the specimen mass thickness and $\mu$ is the linear absorption coefficient; the absorption factor is defined by Equation (12):

$$f(\chi) = \int_0^\infty \frac{\varphi(\rho z) \exp(-\chi \rho z) d\rho z}{\varphi(\rho z) d\rho z}$$

(12)

The fluorescence correction factor $(1 + \gamma + \delta)$ includes the ratio of the fluorescence intensity to the primary characteristic X-ray intensity, $\gamma$, and the corresponding ratio for the continuum fluorescence contribution, $\delta$.

Although most of the characteristic X-ray emission can be explained on the basis of transitions allowed by the selection rules, weak lines may appear which occur as satellites of about 10−20% of the intensity of the parent line and may lie within $\sim$20 eV of the principal line.\(^4\) Their production has been explained by assuming that an atom may be doubly ionized by the incident radiation. The two ionizations have to occur virtually simultaneously since the lifetime of an excited state is very short, $10^{-14}$ s. Usually satellites are relatively more intense for lighter elements because the lifetime of an excited state is longer and the probability of double ionization is higher. Spectral deconvolution accounting for the presence of low- and high-energy satellites and instrumental distortions is required in order to process experimental asymmetric peaks of soft X-ray emission bands. Peak shape changes as a function of the excitation conditions and the matrix composition are related to self-absorption phenomena.

The soft X-ray range can be defined as extending from about 100 eV up to 1.5 keV. For the light elements ($4 \leq Z \leq 9$), in particular, there is no other alternative to using soft X-ray emission. However, soft X-rays may be produced not only owing to electron transitions involving inner orbitals of the atoms but also as a result of transitions associated with outer orbitals containing valence electrons. The overlap of the valence energy states leads to a decrease in X-ray intensity from ionized

**Figure 19** X-ray emission spectra of a high-temperature superconductor YBa$_2$Cu$_3$O$_{z=4}$ ceramic recorded at accelerating voltage of 25 kV by EDS [(a) 1 nA probe current] and WDS [(b−d), 200 nA probe current]. (b) Lead stearate crystal (STE); (c) PET crystal; (d) LiF crystal. The peak of C Kα at 4.47 nm (0.277 keV) in spectrum (b) belongs to a carbon conductive coating deposited on the specimen surface. X-ray spectra (c) and (d) exhibit also the presence of traces of Fe [Fe Kα at 0.194 nm (6.398 keV)] and Pt [Pt Lα at 0.131 nm (9.441 keV)], probably from crucible material.
atoms. Moreover, since the inner levels are relatively discrete compared with the valence band transitions associated with outer orbitals, the low-energy X-ray lines sensitively reflect the energy states of valence electrons. Chemical bonding effects in the soft X-ray emission spectra are usually more pronounced in insulators than in conductors because the binding energies of valence electrons increase from metallic, through covalent, to ionic bonding. At the same time, the energy of the soft X-ray emission correspondingly decreases. Line shifts and change of shape due to the chemical bonding may be observed in the Ka series from the light elements (Z < 10), where the L-shells involved in K–L transitions are incomplete, and also in the L-series from transition metals and their compounds (21 < Z < 28). Analysis of the fine structure of soft X-ray spectra recorded with the appropriate resolution can give not only the elemental composition of an object under study but also important information on electronic structure and bonding.(3) Application of low-energy X-rays to layered specimens enables one to obtain a reduced depth of ionization. It also permits the elimination of most of the secondary X-ray fluorescence emission that occurs when lines of higher energy are employed, particularly for the EPXMA of multiphase specimens. However, quantitative analysis in this case may be complicated by a number of problems such as contamination, coating, background subtraction and line interference.

Bremsstrahlung is produced as a consequence of the slowing of electrons in the Coulomb field of atomic nuclei. The continuous X-rays form a background over an energy range 0 ≤ E ≤ eU extending up to an energy corresponding to the conversion of the entire energy of an incident electron into a radiation photon in a single interaction. The energy distribution of bremsstrahlung may be expressed by Kramers’ equation (Equation 13):\(^{(4)}\)

\[
N(E)\,dE = bZ\frac{E_0 - E}{E}\,dE
\]

where \(N(E)dE\) is the number of photons within the energy interval \(E\) and \(E + dE\), \(b = 2 \times 10^{-9}\) photons \(s^{-1}\) eV\(^{-1}\) electron\(^{-1}\) is Kramers’ constant and \(E_0 = eU\) is the incident electron energy in electron-volts, where \(e\) is the electron charge and \(U\) is the electrostatic potential. The angular distribution of the X-ray continuum is anisotropic and forward peaked. The bremsstrahlung intensity also contributes to the background below the characteristic X-ray peaks, thereby decreasing the peak-to-background ratio; the latter can be improved with increasing energy.
of the incident electron beam. The bremsstrahlung can be used to calibrate the film thickness.

2.6 Cathodoluminescence

Electron bombardment of semiconductors results in the generation of electron–hole pairs leading to the CL emission of photons in the ultraviolet, visible and IR regions. The photons are emitted as a result of electronic transitions between the conduction and valence bands and levels lying in the band gap, which are ascribed to the crystal structure, chemical composition, doping and impurities.Various defects, dopants and surface and external perturbations (temperature, electric field and stress) of the analyzed specimen drastically affect the CL signal. The CL wavelength strongly correlates with the electronic structures, while the CL intensity is a measure of the crystal perfection: it is attenuated when the band structure is perturbed.

2.7 Overview of Instrumentation

TEM/STEM, analytical SEM and EPXMA instruments and specially designed AE microanalyzers equipped with corresponding analytical facilities in order to detect X-rays, inelastically scattered electrons and/or AE are the most important electron-optical instruments for the analytical and structural investigation of the variety of bulk and thin samples. Table 1 contains basic data characterizing state-of-the-art modern AEM techniques.

2.7.1 Analytical Electron Microscopes

A remarkable capability of STEM is the formation of very small electron probes less than 1 nm in diameter by means of a field-emission gun (FEG) and a three-stage condenser–lens system. This enables the instrument to operate in the STEM mode with a resolution determined by the electron probe diameter and sample thickness. The main advantage of equipping a TEM system with a STEM attachment and especially with an FEG source is the possibility of producing a very small electron probe, with which X-ray analysis can be performed on extremely small areas, while switching to operation in the scanning observation modes allows the probe conveniently to be situated on points of interest for analysis.

X-ray generation in thin foils is confined to the small volume excited by the electron probe only slightly broadened by multiple scattering. Better spatial resolution is therefore obtainable for precipitates, or for segregation effects at crystal interfaces, than in an X-ray microanalyzer with bulk specimens, where the spatial resolution is limited to 100–1000 nm by the diameter of the electron interaction volume.

Figure 22(a) and (b) shows an analytical TEM/STEM system. Normally such an instrument involves an FEG, a probe-forming condenser–lens system, an objective lens and an electron detection system (EDS), often together with a PEEL spectrometer. Electron probes of 0.2–0.5 nm in diameter can be formed (Figure 23a and b), the spherical aberration of the lens being the limiting factor in this case. An advantage of STEM instruments is that the contrast can be enhanced by collecting several signals and displaying differences and/or ratios of these by analog or digital processing. Single atoms of heavy elements on an appropriate thin substrate can be imaged with a wide-angle ADF semiconductor detector (Z-contrast) with a higher contrast than in BF- or DF-CTEM modes.

X-ray microanalysis in the STEM mode has a significant advantage over the classical EPXMA in that the lateral resolution can be improved by reducing the illumination area below 1 nm. The fraction of continuous X-ray emission is lower than for bulk samples because of preferential emission in the forward direction. Improvements in X-ray detection have been achieved by increasing the collection angle for a solid state detector up to 0.3 sr and the X-ray count rate up to 29 000 cps by the use of electrostatic blanking, simultaneous X-ray collection from two detectors with equivalent view points and increase in peak-to-background value for the intrinsic germanium detector up to 6300. Determinations of the minimum mass fraction (MMF) for Cr measured on a standard thin film showed that an MMF below 0.1–0.05 wt% is possible. With dedicated STEM instruments, ultrasensitive analysis of a few atoms and at subnanometer lateral resolution has been realized. Owing to the complementary nature of the information obtained, the simultaneous Z-contrast high-resolution imaging and EDS/EELS in a dedicated AEM instrument seem to provide a powerful tool to obtain a deeper insight into a fundamental understanding of correlations between the atomic and electronic structure of materials at the atomic scale.

2.7.2 Electron Probe X-ray Microanalyzers and Analytical Scanning Electron Microscopes

The main task of the EPXMA instrument (Figure 24) is to analyze the elemental compositions of flat, polished surfaces at normal electron incidence with a high analytical sensitivity. The ray diagram of such an instrument is similar to that in SEM, but it contains an additional optical microscope in order to perform fine alignments of the full-focusing wavelength-dispersive spectrometers and to select the specimen points, profiles and/or areas to be analyzed. It contains up to five wavelength-dispersive X-ray crystal spectrometers, which can record different characteristic X-ray wavelengths, and

often also an EDS instrument, which can detect X-rays in a wide energy range. An electron probe (from about 6 nm to 1 µm in diameter is governed by the acceptable probe current range from $10^{-12}$ to $10^{-5}$ A) is produced by a one-, two-, or three-stage demagnification of the smallest cross-section of the electron beam after acceleration. Images are displayed on a cathode-ray tube (CRT) rastered in synchronism. The CRT beam intensity may be modulated by any of the different signals, i.e. SE, BSE, SC, CL or X-rays that result from the electron–specimen interactions.

The combined WDS/EDS microanalyzer is a new-generation EPXMA system that controls its EDS and WDS components with the aid of a powerful computer multitasking workstation and presents X-ray data acquired by both spectrometers and images as a unified analysis result. Combination of WDS and EDS systems can increase the number of simultaneously detectable elements to 13 (five with WDS and eight with EDS). TV display allows the optical microscope image and one of the SEM modes (SE or BSE images) to be observed simultaneously.

Traditionally, electron probe microanalysis (EPMA) or analytical SEM are operated at a high voltage in the range 15–40 kV when used with EDS and WDS.

These conditions are sufficient to allow excitation of X-ray emission of all relevant elements. However, with the increasing interest in the detection of light elements and the availability of ultrathin window or windowless detectors, the importance of low voltages (<1 kV) is also emphasized. With FEGs that produce sufficient current density even in the low voltage range from 5 to 2 kV, the lateral resolution for X-ray analysis may be significantly improved. As a consequence, thin layers and small particles can be examined by SEM without interference of the bulk support.

Utilizing the scanning beam facilities of the EPMA or SEM instrument, panchromatic CL imaging and CL emission spectroscopy may be easily combined with EDS/WDS and X-ray mapping and electron imaging to perform comprehensive spatially resolved microanalysis of point defects in minerals and ceramics and dopant impurities in semiconductors. Environmental scanning
Figure 23 (a) Three-dimensional view of a 0.4 nm (FWHM) electron probe and (b) spot-size measurements at a current of 30 pA using a slow-scan CCD camera. (b) Top left: original image. Top right: lattice image of gold in [100] orientation recorded and displayed at exactly the same magnification as the image of the spot, showing the 0.2-nm spacing for calibration. Bottom left: original image corrected for the response of the CCD camera (beam spreading in scintillator), reducing the apparent spot size by 0.05–0.1 nm. Bottom right: difference between top left and bottom left, showing that the original image is wider (yellow–white ring) and has an extended tail (in blue to black) due to the CCD. (Courtesy of Dr M. Otten, Philips Electron Optics, The Netherlands.)

Electron microscopy (ESEM) is the natural extension of conventional SEM that can operate from high vacuum up to a pressure level that can maintain fully wet specimens. This is promising for microanalytical studies of uncoated insulating specimens by EDS and CL.

Figure 24 Ray diagram of an electron microprobe/analytical scanning electron microscope. in conjunction with morphological characterization by SE/BSE imaging. (29)

2.7.3 Universal Multipurpose Analytical Electron Microscopy Systems

AEM and EPXMA utilize electron excitation for carrying out chemical analysis. A microanalyzer may also be equipped with a cylindrical mirror AE spectrometer; (30) this, however, needs an ultrahigh vacuum. AE microanalyzers, in which the 1–10-keV electron gun is incorporated in the inner cylinder of the spectrometer, can work in the scanning mode so that an image of the surface is formed with SE or an element-distribution map, especially of light elements, is generated using AE (SAM). Digital image processing of multiple detector signals (SE/BSE/SC/AE/X-ray/CL and/or light image) and computer control with the aid of a powerful multitasking workstation, conversion and storage of data, on-line processing for immediate interpretation of images and spectra and feedback to the instrument increase significantly the capability of modern analyzers.

An advanced 300-kV field emission (FE)/AEM system (Argonne National Laboratory) has been designed to attain the best possible analytical sensitivity, resolution and versatility for EDS, EELS, AES, SAED, CBED, scanning transmission ED and reflected high-energy ED.
consistent with state-of-the-art materials research and still provide moderate imaging capabilities in CTEM, HRTEM, STEM and SEM modes. Basically, the system comprises a conventional FEG with gun lens, a triple condenser, objective and quadruple projector. The gun brightness is \( \sim 4 \times 10^9 \text{ A cm}^{-2} \text{ sr}^{-1} \) at 300 kV and the nominal image resolutions in both BF/TEM/STEM modes should be better than 0.3 nm (point-to-point), and better than 0.2 nm in the high-resolution ADF/STEM mode.

Windowless EDS has been optimized to achieve a continuously variable solid angle up to a maximum of 0.3 sr. A hemispherical AES instrument with extraction optics is interfaced to the center of the objective lens and both serial and PEEL detection capabilities will be present. In addition, SE and AE spectrometers are installed within the objective prefield. This universal AEM system may be controlled either directly or using the personal computer and a mouse-directed interactive graphical user interface, thus providing telepresence microscopy remote control and operation over the Internet.(3)

### 3 ANALYTICAL ELECTRON MICROSCOPY METHODS

There are two main spectroscopic systems which can be coupled to SEM, STEM or TEM instruments to record X-ray quanta, i.e. WDS and EDS. Their principal features are compared in Table 2.

\(^a\) Superlattice crystals.(3,4)
0.091 nm) to above 11 nm (Be Ka \approx 11.3 nm). The spot irradiated by the electron beam on the specimen acts as an entrance slit, while the analyzing crystal and the exit slit are mounted on a Rowland circle. The lattice planes of the crystal are bent so that their radius is 2R and the crystal surface is ground to a radius R. Focusing allows a better separation of narrow characteristic lines and a solid angle of collection of nearly 10^{-3}–10^{-2} sr.

Behind the slit, X-ray photons are recorded by a proportional counter and their energy is converted to a voltage pulse. The detection efficiency of the Bragg reflection and of the proportional counter is about 10–30\% \(4,12\). The number of electron–ion pairs generated in the counter is proportional to the quantum energy \(E = h\nu\). The pulses are further amplified, discriminated in a single-channel analyzer and counted by a scaler. The pulse intensity per second is indicated by a ratemeter. Advanced counters with ultrathin Mylar windows are available to detect the weak Ka lines of light elements \(4 \leq Z \leq 11\) more efficiently than with EDS. WDS systems offer better energy (wavelength) resolution and higher count rates (above 50 000 cps) than EDS systems but require a higher beam current (see Figure 19a–d and Table 2). For scanning across a chosen spectral region, the counter and the analyzing crystal should be moved by a pivot mechanism. Usually X-ray microanalyzers are equipped with several WDS instruments, which enable different wavelengths to be recorded simultaneously.

With EDS, a solid-state detector is positioned before the dispersing system to collect the distribution of X-ray emission in a wide energy range \([0.1–40\text{ keV}\) for a conventional Si(Li) detector and even up to 80 keV for an intrinsic Ge detector\]. Dispersion of the signal detected then takes place by the electronic processing using pulse-height amplification, pileup rejection of possible coincidence of pulses and sorting by a multichannel analyzer, which relates the measured pulse height to the energy of the incoming photon. The entire assembly of a conventional detector, including a field-effect transistor preamplifier, is cryo-cooled under vacuum at near liquid nitrogen temperature to minimize any thermally induced signals. The detection efficiency of an Si(Li) detector is nearly 100\% in the range 3–15 keV. The decrease at low energies is caused by the absorption of the X-rays in the thin Be window separating the high-vacuum microscope column from the detector. Both windowless and ultrathin window detectors can record K\alpha quanta from light elements down to Be. At energies higher than 15 keV the decrease in the efficiency is caused by the increasing probability of penetrating the sensitive layer of the detector without photoionization.

Recent developments in EDS detector fabrication have resulted in significant characteristic improvements in low-energy performance and sensitivities. Modern EDS detectors can also be exploited without permanent cooling; they can be kept at room temperature without any degradation in performance. Newly designed models are electrically cooled with an incorporated Peltier device or need no cooling at all, although still at the cost of some decrease in the resolution. The development of a new microcalorimeter EDS detector with an energy resolution of \(3–10\text{ eV}\) allowed detection not only of closely spaced X-ray peaks but also of chemical shifts, although the counting rate is still rather low\(31\)

Unlike WDS, where the irradiated point has to be carefully adjusted on the Rowland circle, an EDS instrument does not need any mechanical adjustment, and therefore can be used much more effectively for profile or area analyses by scanning over large and/or rough specimens. Since an EDS system occupies a smaller space than a WDS system, it is commonly used in analytical SEM and TEM/STEM set-ups. A further advantage of EDS is that most of the characteristic X-ray lines can be recorded simultaneously in a short time. For this reason, X-ray microanalyzers that work with WDS are often also equipped with an EDS instrument under the control of the same computer, thus forming an integrated WDS/EDS system in order to provide more rapid and accurate assessments of the specimen elemental composition. This includes: simultaneous data acquisition of up to 13 elements with the combination of five WDS and one EDS instruments, which is more than twice the number measurable with WDS alone; microanalysis of light elements and microvolume elements with a high beam current of \(10^{-9}–10^{-5}\text{ A (WDS)}\) and of heavy elements of a few percent under the same conditions as for SEM observations at a current of \(10^{-12}–10^{-9}\text{ A (EDS)}\) for increasing the total analysis efficiency; and preliminary evaluation of beam-sensitive samples by EDS.

### 3.2 Cathodoluminescence Spectroscopy in the Scanning Electron Microscopy, Scanning Transmission Electron Microscopy and Transmission Electron Microscopy Modes

CL is a powerful technique that provides microcharacterization of the optical and electronic properties of luminescent materials with a detection limit as low as \(10^{14}\text{ atoms cm}^{-3}\) and a spatial resolution down to 10 nm and even less for adsorbed or thin specimens. Owing to the scattering of the beam electrons and the large escape depth of light, the spatial resolution may not reach that of an SE image. CL is a well-established technique in SEM\(12,25\) although the CL signal can, of course, also be collected in a TEM/STEM system equipped with a detector for the light quanta. An advantage of CL is the possibility of simultaneously imaging crystal defects including depth-resolved information by
varying the beam energy and examining their CL nature. Additional information concerning variations in the concentration of dopants acting as luminescence centers and recombination centers is obtainable. The CL intensity is usually low and requires a highly efficient light-collection system with a large solid angle and lateral selection of the irradiated area to avoid the contribution of diffusely scattered electrons.

EELS measures the energy distribution of electrons which have been transmitted through a specimen. EFTEM/EELS using an imaging filter or magnetic sector spectrometer offer possibilities to select electrons with a well-defined energy loss (zero-loss, plasmon and elemental imaging on inner-shell ionization edges) and to record spatially and angularly resolved EEL spectra providing local analyses of plasmon losses and inner-shell excitations with ELNES and EXELFS.\(^2\) The transferred energy can be recorded as an energy loss of the incident monochromatic electrons and reduces their kinetic energy to \(E_0 - \Delta E\). This results from excitations from occupied states below the Fermi level to unoccupied states above it, allowed by selection rules. Indeed, EELS is spectroscopy of excited electron states beyond the Fermi level. An EEL spectrum (Figure 25a and b) is more complicated than an X-ray emission spectrum and contains information from several excitation processes.\(^1\)

Always being delocalized to some extent, inelastically scattered electrons considerably reduce the image contrast. Furthermore, the chromatic aberration of the objective lens also reduces the resolution for thicker specimens. The great advantage of energy filtering is that it allows the separation of the contribution of inelastically scattered electrons from that of elastically scattered electrons and selection of inelastically scattered electrons with certain energy losses. With column-incorporated and postcolumn imaging filters, a new era of AEM began. The different operating modes of the EFTEM/EELS instrument usually are combined in order to switch easily between ESI and electron spectroscopic diffraction (ESD) to different EELS modes. Because electron images and diffraction patterns as projections of the reciprocal lattice represent two-dimensional intensity distributions, selection of energy losses with an appropriate energy window allows a new dimension in EM (spectrum imaging and image-spectrum techniques\(^{10,11}\)). Furthermore, an upgrading of the initially developed serial detection system, which comprises a slit, a scintillator and a photomultiplier connected to a multichannel analyzer, by the parallel array of typically 1000 diodes, which measures all the spectral channels in parallel, became a major breakthrough in terms of detection efficiency.

4 DIGITAL IMAGE ANALYSIS

Image analysis converts the information in the electron image into numerical form. In addition to on-line image acquisition, this is usually also off-line or on-line gray-scale processing, discrimination and binarization followed by quantitative evaluation of features of interest. Processing of data may vary in a wide range from size/shape population distributions, stereological measurements, image reconstruction and specimen restoration to fractal analysis.\(^{1,12,32,33}\) The next important application of image analysis (see section 2.2.10) is simulation, and matching of conventional and HRTEM lattice images and diffraction patterns, particularly by multislice calculations, taking into account the contrast transfer function, astigmatism and beam tilt correction.\(^{12,33}\) Some specific applications of image analysis in AEM will be considered in section 7.

5 SAMPLE PREPARATION TECHNIQUES

Sample and standard preparation for AEM includes a variety of techniques commonly used for specimen preparation in conventional EM, although with some

6 QUANTIFICATION

6.1 X-ray Microanalysis

In order to quantify X-ray spectra, the measured intensity of a particular characteristic X-ray line from the bulk specimen should be compared with the same one produced by a reference bulk standard of known composition. The procedure involving the use of bulk pure-element standards for EXPMA of bulk specimens can, in principle, also be adapted for the microanalysis of thin films\(^{(14,12)}\). Hence, by keeping instrumental settings (probe current, high voltage, detector efficiency, etc.) constant, while the X-ray intensity readings are being taken with dead time corrections related to the spectrometer, one can consider the ratio of the X-ray intensities of the \(i\) line of an element \(a\), \(k_a^i\), measured respectively in the specimen, \(I_{sp}^i\), and a standard, \(I_{st}^i\) (Equation 14):

\[
\frac{I_{sp}^i}{I_{st}^i} = k_a^i
\]

where the intensity ratio can be related to the mass concentration, \(c_a\), of the analyte element as \(k_a = f(c_a)\) and \(c_a = 1\).

An accurate quantitative evaluation can be performed if the \(k_a^i\) ratio is corrected for various effects: the atomic number correction for the differences between the electron scattering and penetration in the sample and the standard; the absorption correction for the difference in the absorption of the emitted X-rays as they pass through the sample or standard; and the fluorescence correction for the secondary X-ray fluorescence generated by the X-ray emission in the specimen and in the standard.

6.1.1 ZAF Method

The ratio of X-ray intensities emitted from element \(a\) in the specimen and in the pure standard is given by
Equation (15):

\[
\frac{I_{\text{sp}}^a}{I_{\text{st}}^a} = \frac{\int_{0}^{\infty} \psi(\rho z) \psi(\rho z'_{\text{st}}) \rho dz}{\int_{0}^{\infty} \psi(\rho z) \rho dz} \int_{0}^{\infty} f(x)_{\text{sp}} (1 + \gamma + \beta)_{\text{sp}} \rho dz = \frac{Q w(N_{c_{a}}/A) \rho dz}{Q w(N/A) \rho dz} = c_a
\]

where \( Q \) is the ionization cross-section of atoms \( a \), \( w \) is the X-ray emission yield, \( N \) is Avogadro’s number, \( A \) is the atomic weight of element \( a \), and \( c_a \) is the mass concentration of element \( a \) in the specimen. Then one can easily deduce from Equation (15) that the next three ratios may be used to represent the atomic number, absorption and fluorescence correction factors, \( k_Z, k_{\Lambda} \) and \( k_f \), respectively. The corresponding corrections are considered in the ZAF method as independent multiplicative factors of the \( k_a \) ratios (Equation 17):

\[
k_a^i = k_Z k_{\Lambda} k_f c_a
\]

The atomic number correction should be applied to the \( k_a \) ratio to compensate for the difference between the electron retardation and electron backscattering in the specimen and the standard. Because each correction factor is a function of \( c_a \) rather than \( k_a^i \), iteration procedures (normalization, hyperbolic or Wegstein methods) should be employed in order to improve further the precision of the data.\(^{4}\) The \( k_Z \) for element \( a \) can be written as Equation (18):

\[
k_a^i = \frac{R_{\text{sp}}^a}{R_{\text{st}}^a} \frac{E_0}{E_a} \left( \frac{Q/S}_{\text{sp}} \right) dE \int_{E_a}^{E_0} \left( \frac{Q/S}_{\text{st}} \right) dE
\]

where the terms \( R \) and \( S \) refer to the electron backscattering and the electron stopping power, respectively, and \( Q \) is the ionization cross-section. The integral limits are from the incident electron beam energy \( E_0 \) to the critical excitation band \( E_a \) for the chosen X-ray line of \( a \). The electron stopping power \( S = -1/\rho dE/dx \), defined as the energy lost per unit electron path length in material of density \( \rho \), may be approximated according to Equation (19):\(^{5}\)

\[
S = 78500 \frac{Z^2}{A^2} \frac{1}{E^a} \ln \left( \frac{1.166E}{J} \right)
\]

where \( J = [10.04 + 8.25 \exp(-Z/11.22)] Z \). The expressions for the ionization cross-section \( Q \) have the general form of Equation (20):

\[
Q = C \frac{\ln U}{U_{Z^2}}
\]

where \( C \) is a constant and \( U = E_0/E_a \) is the overvoltage.

The electron backscattering factor \( R = (1 - l_0)/l_0 \), defined as the fraction of total generated X-ray intensity excluding loss due to BSE, may be calculated using empirical expressions. In a multielement system, the factor \( R \) for element \( i \) may be derived from Equation (21):

\[
R_i = \sum_j c_j R_{ij}
\]

where \( i \) represents the element being measured and \( j \) denotes the elements in the specimen including \( i \); \( R_{ij} \) is the backscatter correction factor for element \( i \) in the presence of element \( j \). Several tabulations and fitted polynomial expressions are available to estimate values of \( R \) for various elements as a function of \( Z \) and \( U \).\(^{36}\)

The absorption correction factor \( k_A = f(x)^a_{\text{sp}}/f(x)^a_{\text{st}} \) reflects the attenuation of the X-ray intensity measured by the detector. The basic formulation for the absorption term \( f(x) \) is given by the Philiber–Duncumb–Heinrich equation (Equation 22):\(^{4}\)

\[
\frac{1}{f(x)} = 1 + \frac{\chi}{\sigma} \left( 1 + \frac{h}{1 + h} \right)
\]

where \( \sigma = 4.5 \times 10^5 / (E_{c_{1,65}^a} - E_{c_{1,65}^a}) \) is Lenard’s constant and \( h = 1.2A/Z^2 \).

The variable \( h \) is dependent on the composition and must be averaged over the various elements present in multielement specimens according to Equation (23):

\[
h_i = \sum_j c_j h_j
\]

In addition, the mass absorption coefficient \( \mu/\rho \) for the characteristic line of element \( i \) must be the weighted sum over all elements, i.e. (Equation 24):

\[
\left( \frac{\mu}{\rho} \right)_{i}^{\text{sp}} = \sum_j c_j \left( \frac{\mu}{\rho} \right)_{j}^{i}
\]

The calculation of \( f(x) \) from Equation (22) is most accurate for values greater than 0.7.

The characteristic fluorescence correction is necessary when the energy \( E_i \) of the characteristic X-ray line from an element \( j \) is greater than the critical excitation energy \( E_{c_{1,i}} \) for an element \( i \) and when the difference \( E_i - E_{c_{1,i}} < 0.5 \text{ keV} \). This may result in excitation of the characteristic emission of element \( i \) by the corresponding
characteristic line of element \( j \). The basic formulation of the characteristic fluorescence correction is given by Equation (25):

\[
F_i = \frac{1 + \sum I_{i,j}^f/I_i}{1 + \sum I_{i,j}^p/I_i}^{sp}\tag{25}
\]

where \( I_{i,j}^f/I_i \) is the ratio of the characteristic intensity of element \( i \) excited by fluorescence to the electron-excited intensity. The total correction should be summed over all the elements in the specimen. In practice, when the standard is either a pure element or there is no significant fluorescence of element \( i \) by other elements in the standard, Equation (25) can be simplified to Equation (26):

\[
F_i = \frac{1 + \sum I_{i,j}^f/I_i}{1 + \sum I_{i,j}^p/I_i}^{sp}\tag{26}
\]

In addition, the calculation of the continuum fluorescence is relatively complicated, involving integration over the range from \( E_0 \) to \( E_c \) for each element in the sample. When \( f(\chi) > 0.95 \), \( c_i < 0.5 \) and \( Z_{sp} \neq Z_{st} \), the correction can be as large as 2–4\%, and it should be included for highest accuracy.

6.1.2 \( \phi(pz) \) Methods

Quantitative microanalysis can be carried out more suitably by treating the atomic number and absorption factors together rather than as separate entities. The correction by the \( \phi(pz) \) procedure is based on the integration of X-ray distributions, \( \phi(pz) \) curves; it is attractive for the analysis of low-energy X-ray lines, where \( f(\chi) \) is much less than 0.7 and the accuracy of the ZAF method is low. However, results of the analysis based on the \( \phi(pz) \) methods are dependent on the accuracy of description of the experimental \( \phi(pz) \) curves (especially in the case of systems with unknown X-ray depth distributions) and/or fitting to the corresponding results of Monte Carlo simulation.

For instance, the Packwood–Brown model utilizes a modified surface-centered Gaussian function to describe the shape of \( \phi(pz) \) curves. The Gaussian nature of the curve implies some random distribution of electron scattering events. The surface modification should be applied to take into account that the incoming accelerated electrons require some finite distance range before becoming randomized. The general expression for \( \phi(pz) \) is given by Equation (27):

\[
\phi(pz) = \gamma \exp[-\alpha^2(pz)^2] \left[ 1 - \left( \frac{\gamma - \phi(0)}{\gamma} \right) \exp(-\beta pz) \right]
\]

The Gaussian is modified by a transient function to model an increase of the X-ray production away from the near-surface region. The coefficient \( \alpha \) relates to the width of the Gaussian and \( \gamma \) relates to the amplitude. The term \( \beta \) in the transient is related to the slope of the curve in the subsurface region: this means the rate at which the focused electron beam is randomized through scattering in the sample. The intercept \( \phi(0) \) is related to the surface ionization potential. The \( \alpha, \beta \) and \( \gamma \) parameters are expressed in terms of several different experimental terms, i.e. elemental composition of the sample, incident electron energy, atomic number, etc.

6.1.3 Standardless Analysis

In standardless analysis, the measured standard intensities are substituted with calculated values based on atomic data and empirical adjustments to experimental data. Better quantitative procedures were developed in the last decade to validate better standardless calculations. In particular, with the K-lines a relative accuracy of 1–5\% is reached. Some uncertainties exist with the L-lines and especially with the M-lines where atomic data sets are still incomplete or not accurate enough. Further study of the effect of the incompletely filled inner shells is necessary to obtain better atomic data.

The X-ray intensity generated in a bulk sample (standard) for the simpler case of the K-line may be expressed by Equation (28):

\[
I = g(pw) f(\chi) N A R E E_c Q dE/d\psi dE\tag{28}
\]

where \( g \) is a normalization factor that depends on the experimental parameters (beam current, acquisition time, solid angle of the detector, etc.), \( \varepsilon \) is the detector efficiency, \( p \) is the transition probability, \( w \) is the fluorescence yield, \( f(\chi) \) is the absorption correction, \( R \) is the backscatter factor and \( Q \) is the ionization cross-section given in general form by Equation (20). The additional intensity induced by the secondary X-ray fluorescence is not considered here. When calculating the number of ionizations for the L- and M-shells, both direct ionizations induced by the bombarding electrons and indirect ionizations caused by the nonradiative Coster–Kronig transitions between subshells prior to the emission of the X-ray line must also be taken into account. The Si(Li) detector efficiency may be given by Equation (29):
The $k$ ratios obtained by comparing experimental spectra with calculated standard intensities may be used as concentrations of first approximation following the spectra with calculated standard intensities may be used where $K$, the measured fraction of total series intensity, $t$ is the film thickness and $A_i$ is the atomic weight of element $i$. To avoid the influence of the substrate, the particles should be scanned in a raster because in general the uniformity of the beam density cannot be assured when the probe diameter is comparable to or larger than the particle size.

In practice, it is suitable to measure the relative concentration of element $i$ to another element $j$ which may be given by Equation (31):\(^{(38)}\)

\[
\frac{c_i}{c_j} = k_{ij} \frac{I_i}{I_j}
\]

where $c_i$ and $c_j$ are the mass concentrations of elements $i$ and $j$, respectively, $I_i$ and $I_j$ are their corresponding X-ray line intensities and $k_{ij}$ is the Cliff–Lorimer sensitivity factor. The sensitivity factors can be related to an inner standard element by Equation (32):

\[
k_{ij} = \frac{k_{i,\text{in}}}{k_{j,\text{in}}} = \frac{k_i}{k_j}
\]

where $k_{i,j,n} = k_{i,j}$ are the relative sensitivity factors. The index is usually referred to silicon and iron commonly used as internal standard (is) elements. The tabulated experimental values of the sensitivity factors for K-, L- and M-line emission from various elements are available.\(^{(38,41)}\) It is also possible to calculate the sensitivity factors using a set of parameterized equations.\(^{(37,42)}\)

Equation (31) may be expanded to take into account the effects of absorption and fluorescence as follows (Equation 33):

\[
\frac{c_i}{c_j} = k_{ij} \frac{I_i}{I_j} \frac{k_a}{1 + I_i/I_0}
\]

where $I_i$ and $I_0$ are the fluorescent and primary X-ray intensities of $i$, respectively, and $k_a$ is the absorption factor given by Equation (34):\(^{(36)}\)

\[
k_{a} = \frac{(\mu/\rho)p_t}{(\mu/\rho)p_f} \frac{1 - \exp[-\chi^2(\rho t)]}{1 - \exp[-\chi^2(\rho t)]}
\]

The parameterless extrapolation method proposed by Van Cappellen\(^{(43)}\) is based on measurements of the relative intensities $I_i/I_j$ at various thicknesses following extrapolation to zero thickness ($I_j = 0$) by plotting $I_i/I_j$ versus $I_i$. Then, if the secondary emission of the elements is much smaller than the primary emission, the mass concentration ratio can be determined, such as (Equation 35):

\[
\frac{c_i}{c_j} = k_{ij} \lim_{t \to 0} \frac{I_i}{I_j}
\]

Other methods based particularly on convergence between two or more different measurements for simultaneous determination of film composition and thickness and Monte Carlo techniques are discussed in the literature.\(^{(4,14,36,37)}\)

### 6.2 Electron Energy-loss Spectroscopy

Multiple scattering can alter the EEL spectrum (Figure 25a and b, curve 1), taking the form of one or more low-loss excitations if the specimen thickness is of the order of or more than the estimated inelastic mean free path. Multiple scattering effects can be removed from the spectra using a number of procedures, although the most commonly employed procedures are based on fast Fourier transforms and are known as Fourier-log and Fourier-ratio techniques.\(^{(44)}\)

For Fourier-log deconvolution, the recorded spectral intensity may be written in the form of Equation (36):\(^{(45)}\)

\[
J(E) = \sum_n C_n [R(E) \otimes S_n(E)]
\]
where \( R(E) \) is a unit-area resolution function, \( \otimes \) represents a convolution with respect of energy loss, \( S_n(E) \) is the \( n \)-fold self-convolution of the single scattering distribution (SSD), \( S(E) \), and the Poisson coefficient \( C_n = \ln(n)/n! \).

The Fourier transform of Equation (36) gives a simple product, and taking into account that the zero-loss profile \( Z = I_0 R \), one can obtain Equation (37):

\[
j(v) = \sum C_n r(v) [s(v)]^n = I_0 r(v) \exp \left( \frac{s(v)}{I_0} \right)
\]

The SSD (Figure 25a and b, curve 2) may be computed as the inverse Fourier transform of Equation (38):

\[
s(v) = I_0 \ln \left( \frac{j(v)}{z(v)} \right)
\]

where \( j(v) \) and \( z(v) \) are the Fourier transforms of the experimental EEL spectrum and of the zero-loss peak, respectively.

For quantitative EELS, the number of atoms of element \( i \) per unit area may be obtained as Equation (39):

\[
n_i = \frac{1}{\sigma_i(\alpha, \Delta)} \frac{N_i(\alpha, \Delta)}{N_0(\alpha, \Delta)}
\]

where \( \sigma_i(\alpha, \Delta) \) is the partial cross-section for ionizations which result in scattering of the PE within \( 0 \leq \theta \leq \alpha \) and the energy-loss region with an energy window of width \( \Delta E_1 \leq \Delta E \leq \Delta E_1 + \Delta ; N_0 \) and \( N_i \) are the number of electrons in the range \( 0 \leq \Delta E \leq \Delta \) and \( E_1 \leq \Delta E \leq E_1 + \Delta \), respectively.

As in X-ray analysis, a ratio method is utilized to determine the relative number of atoms \( n_i/n_j \) of two elements (Equation 40):

\[
\frac{n_i}{n_j} = \frac{N_i \sigma_i(\alpha, \Delta)}{N_j \sigma_j(\alpha, \Delta)}
\]

7 APPLICATIONS

Examples selected in this section demonstrate some methodological innovations and practically important applications of AEM and scanning microanalysis such as advanced EPXMA particle analysis of populations of mixed silver halide microcrystals of contemporary industrial photographic emulsions under cryogenic conditions (section 7.1), combined X-ray compositional mapping (section 7.2.1), EELS spectrum-imaging and image-spectrum (section 7.2.2) and local specimen thickness determination (section 7.3).

7.1 Automated Population Analysis: Size–Thickness–Elemental Composition

Figure 26(a–c) shows (a) a typical X-ray spectrum, (b) some results on elemental compositions which result in scattering of the PE within \( 0 \leq \theta \leq \alpha \) and (c) iodine content of the population as a function of crystal diameter (\( \mu m \)) and thickness (nm). Background fitted by least squares is shown in (a).
(c) thickness analyses obtained by cryo-EPXMA for 700 Ag (Br, I) microcrystals of a contemporary industrial photographic emulsion.\(^{146}\) A JEOL JXA-733 electron microprobe operating at a 25 kV accelerating voltage and 1 nA beam current was equipped with a Noran Si(Li) EDS detector placed at a take-off angle of 40°, a Wolf–Everhart BSE detector, an Everhart–Thornley SE detector, a scintillator TE detector and a transmission specimen holder. The crystal size was determined by SE/BSE imaging, the thickness was estimated from the BSE intensity and the X-ray spectra provided the required composition information. However, in order to perform automated analyses, several serious problems had to be overcome. First, the AgX (X = Br, I) microcrystals are not only sensitive to light irradiation, but also degrade rapidly under the influence of the electron beam. Under normal analysis conditions, the crystals are often destroyed within seconds owing to the partial evaporation of halogens. Lowering the sample temperature to about −190 °C by the use of a liquid-nitrogen-cooled Oxford C10001 cryo-stage increased the resistance against radiation damage, thus allowing an X-ray analysis during 20 s or more.

Sample cooling inevitably caused sample drift; large temperature differences inside the microprobe instrument led to metal shrinkage, which in turn resulted in unpredictable motion of the sample under the electron beam. This drift continued for several hours after sample insertion and was far too large (about 50 nm min\(^{-1}\)) for the usual particle analysis software; indeed, the detected particles had moved away from their detected position before their X-ray spectrum acquisition even began. The problem was resolved by employing an original algorithm, which detects and analyzes particles sequentially during (and not following) the BSE image acquisition.

Particles were distinguished from the background by selecting a threshold value. To avoid missing small or very thin crystals, the threshold value was set as close to the background as possible. Owing to the limited sharpness of the BSE image, however, this might sometimes cause an overestimation of the projected area or diameter of the crystal. An accurate area determination was achieved by setting a second threshold value, different for every particle, halfway between the background image brightness and the maximum particle brightness. If the number of particle pixels rejected by this second threshold was too large, this was considered as an indication that the detected structure was in fact composed of overlapping particles. Therefore, it was eliminated from the analysis. The occurrence of large shape factor (perimeter\(^2\)/4π × area) values indicates touching or overlapping of crystals; they were also eliminated.

Since the crystals were very thin and high beam currents were undesirable because of possible crystal destruction, the X-ray emission was relatively low. Therefore, a large 30 mm\(^2\) area Si(Li) detector placed as close as possible to the sample was used. The crystals were mounted on a very thin supporting foil (e.g. carbon foil on copper grid) using a transmission holder in order to reduce the bremsstrahlung background. Net peak intensities used for the accurate determination of the crystal composition were obtained by means of least-squares fitting.

### 7.2 X-ray and Electron Energy-loss Spectroscopic Elemental Mapping

#### 7.2.1 X-ray Mapping

X-ray maps provide valuable information on two-dimensional elemental distributions over bulk or thin samples.\(^{13,33,36}\) X-ray mapping can be undertaken with both EDS and WDS, where incoming counts for elements of interest are fed back into the SEM or STEM instrument. The X-ray analyzer takes control over the electron beam via a special interface, driving the beam around in a rectangular frame and collecting the X-ray emission for each pixel separately. An external beam deflection interface allows X-ray mapping by beam rocking also on TEM instruments using the standard hardware and software. In the case shown in Figure 27, combined WDS/EDS X-ray composition maps of an Na–Al–Si–Ca–Fe–Zr–Sn–O ceramic were acquired on a JEOL JXA-8900 WDS/EDS combined automated microanalyzer operating at 15 kV accelerating voltage. The simultaneous composition measurements of eight constituent elements by EDS (Al, Si, Fe, Sn) and by WDS (O, Na, Ca, Zr) and BSE imaging in a “compo” mode were performed on a 140 × 140 μm\(^2\) area.

Color compositional maps represent spatially resolved X-ray multielemental analysis within the chosen region of the sample. However, it is often difficult to visualize the compositional ranges and resulting interelement correlations from the map, particularly for minor or trace constituents. As an alternative method, a composition–composition histogram displaying the numerical relationship between concentrations of the components at various points of the sample can be proposed.\(^{36}\)

The SE/BSE images are normally used to select regions for subsequent X-ray mapping. If features of interest are not differentiated in the monochrome black–white electron image then they can easily be overlooked for further analysis. Using the X-ray spectrum detected by EDS, one can construct a color response directly related to the underlying elemental composition where the spectrum from each compound has a characteristic...
color. Thus, topography and elemental composition of a specimen are compressed into a single view. Furthermore, using this technique it is not necessary to monitor the X-ray spectrum, set windows or collect X-ray maps. Compositional data even in samples with a rough surface are automatically acquired into the SEM images because the colors displayed always relate to the sample composition. 

7.2.2 Electron Energy-loss Spectroscopic Spectrum-imaging and Image-spectrum

Using a PEEL spectrometer (and/or EDS) fitted to a dedicated STEM instrument (FEG-VG H501) and/or TEM/STEM (a Hitachi H700H and a Philips EM430 were first used), a large four-dimensional data array may be recorded, which corresponds to electron intensity within a three-dimensional (x, y, E) space, one independent scattering angle dimension and a dependent counts dimension. Here x and y are image coordinates and E is the selected energy loss. A similar series of energy-filtered images at different energy losses can be also acquired using EFTEM (Zeiss computerized EM902 and Zeiss (Leo) EM912 Omega) equipped with an imaging filter (imagespectrum).

These techniques enable one to collect a very large amount of information for subsequent off-line processing in order to subtract the pre-edge background, to calculate local thickness and, to perform mean least-squares fitting, deconvolution and Kramers–Kronig analyses. The data may be displayed as line scans, two-dimensional arrays of spectra or two-dimensional images of elemental concentration, thickness, complex dielectric permittivity, etc.

7.3 Sample Thickness Determination

A need for the determination of the local specimen thickness is associated with absorption and/or fluorescence corrections and estimation of the spatial analysis resolution (EDS) and with multiple scattering corrections (EELS). Several means for measuring specimen thickness have been proposed (Table 5), but no one technique has been recognized as universal, although methods based on absorption of X-rays, EELS and CBED may be recommended because they provide possibilities for automated on-line procedures.

8 CURRENT TRENDS

The last decade has shown considerable progress in the theoretical description of fundamental electron–solid interactions and methodology of AEM, especially on standardless and fully quantitative procedures, automatic instrumentation, low-voltage microanalysis

of light elements and super-high-sensitivity analysis at nanometer and subnanometer lateral resolution as well, which have been briefly discussed in this article.

Nowadays, there is a tendency to develop integrated multipurpose AEM systems based on TEM/STEM and/or SEM systems equipped with multiple detector systems and to detect the effects of inelastic interactions of electron beams within the object (WDS, EDS, PEEL spectroscopy, ESI, AES/SAM). On the other hand, standard modes, in particular electron X-ray diffraction methods (SAED, CBED, electron channeling, Kikuchi patterns), DF and stereo observations, are, of course, still widely used. As a result, conventional TEM, STEM and SEM instruments have evolved from a purely imaging/diffraction instrument into a true AEM tool using most of the signals produced in the course of electron beam–sample interactions, although for ultimate performance it is mostly better to optimize an instrument for that particular purpose (for instance, as in the case of a dedicated STEM instrument). In HRTEM and STEM Z-contrast modes spatial resolution (~0.1 nm) has steadily reached the atomic level. In high-resolution FE/SEM one can achieve resolution of medium-resolution TEM but for bulk specimens. Further developments indicate rapid progress towards atomic-level analytical resolution. These significant improvements became possible by the introduction of very bright electron sources (FEG, ~10⁸–10⁹ A cm⁻² sr⁻¹), capable of producing fine electron probes less than 0.2 nm in diameter. This capability has dramatically boosted both imaging and analytical AEM modes.

Development of PEEL detection systems based on CCD offers better detection limits; they allow one to investigate with much higher efficiency not only the low losses but also the more local and less intense core losses up to 3000 eV. An integral energy filter is fast becoming a standard option on the latest generation of AEM instruments owing to the rising importance of EFTEM/EELS for novel imaging techniques such as elastic contrast, energy-loss tuning and high-resolution electron spectroscopic elemental mapping. The development of a new microcalorimeter EDS system with an energy resolution of 3–10 eV allowed the detection not only of closely spaced X-ray peaks but also of chemical shifts. Hence the versatility of AEM, combining high-resolution imaging in different modes and powerful analytical facilities, the variety of signals and contrast effects available in the course of electron beam–specimen interactions, establish it as an outstanding tool for universal applications in chemistry and materials science.

1. A light beam is generated in a known polarization state.
2. The beam is reflected from or transmitted through a sample having specularly reflecting plane-parallel surfaces, leading to a linear (frequency-conserving) interaction that changes the polarization state.
3. The polarization state of the reflected or transmitted beam is measured.
4. Parameters are determined that characterize the interaction in terms of the change in polarization state.
5. From these parameters, information about the sample is deduced, including its optical properties, or the thickness and optical properties of a thin film on the surface of the sample.

Steps 1–3 involve set-up and operation of instrumentation whereas step 4, data reduction, is generally performed on-line by computer during measurement. Step 5 is usually performed after measurement, unless ellipsometry is being applied for real time process control.

Several variations of the ellipsometry experiment have been developed. The most common is reflection ellipsometry, in which the polarization state change is measured upon oblique reflection of the light beam from a specularly reflecting sample. For an isotropic sample, the parameters describing this interaction are \((\psi, \Delta)\), defined by \(\tan \psi \exp(i\Delta) = r_p/r_s\), where \(r_p\) and \(r_s\) are the complex amplitude reflection coefficients for linear \(p\) and \(s\) polarization states. In these states, the electric field vibrates parallel and perpendicular to the plane of incidence, respectively. In spectroscopic ellipsometry (SE), \((\psi, \Delta)\) are measured continuously versus wavelength over a spectral range designed for sensitivity to the physical and chemical features of interest. In real time ellipsometry (RTE), \((\psi, \Delta)\) are measured versus time at fixed wavelength using a time interval designed to follow the kinetic processes of interest. The latter two modes can be combined to yield real time spectroscopic ellipsometry (RTSE), utilizing parallel detection at many wavelengths simultaneously. In imaging ellipsometry (IE), \((\psi, \Delta)\) are measured over a two-dimensional area of a nonuniform sample surface using a resolution designed to detect feature sizes of interest.

Because the polarization change is determined in an ellipsometry measurement, rather than the irradiance change as in a reflectance measurement, ellipsometry is a very high precision technique for characterizing the optical properties of materials and thin films, as well as the thicknesses of thin films. The \(p–s\) phase shift difference \(\Delta\) provides exceptionally high sensitivity to changes in the thickness of a thin film on a specular surface. In fact, changes on the order of hundredths of a monolayer in surface coverage can be detected. A primary advantage of ellipsometry is its ability to obtain data noninvasively from samples immersed in any medium that is transparent to the light beam. Thus, numerous in situ and real time applications exist in disciplines such as physics and chemistry, materials and surface science, electrical and chemical engineering, electrochemistry, and...
biochemistry. In contrast, analytical techniques based on electron spectroscopies, for example, are only effective in high vacuum environments; thus, in vacuo instrumentation is required.

Limitations of ellipsometry arise from restrictions on the nature of the sample, as well as from the difficulties of data analysis, particularly for complex samples e.g. those exhibiting nonuniformities over the area of the probe beam. To avoid measurement difficulties as a result of light scattering and to simplify data analysis, reflecting surfaces should be specular and free of optical nonuniformities on an in-plane scale greater than about one-tenth of the wavelength of the incident beam. Nonuniformities on a scale greater than the wavelength can be detected by IE; in other measurement modes the sample should be uniform over the beam area for ease of data analysis. In addition, characterization of films that are thinner than the thickness of the roughness modulations on the substrate surface is difficult since data analysis relies on optical models consisting of multilayer stacks with plane-parallel interfaces. Recent progress has been made in ellipsometry research that addresses the analysis of complex samples.

The most widely used instruments for SE and RTSE span the spectral range from the ultraviolet (200–300 nm) to the near-infrared (800 nm). Over this spectral range, the optical properties deduced from SE provide information on the processes of absorption and dispersion originating from the valence electron transitions. Specialized SE equipment designed for the infrared range can be more effective for chemical identification of thin films, based on the absorption processes originating from the bond vibrational modes.

1 INTRODUCTION

The analytical technique of ellipsometry derives its name from the measurement of the ellipse of polarization that is generated when a polarized light beam interacts with a sample under analysis.¹ The instrument that performs this measurement is called an ellipsometer. The ellipsometry experiment entails five steps:

1. generation of a light beam in a known state of polarization using optical elements such as polarizers and compensators (or retarders),
2. frequency and wavefront-conserving interaction of the beam with a sample leading to an emergent beam in a second polarization state,
3. full or partial characterization of the second polarization state,
4. determination of parameters that characterize the interaction from the information on the two polarization states and
5. deduction of information on the sample, such as optical properties and film thicknesses, from the interaction parameters.

As a result of the interaction, the light beam may emerge by transmission through the sample (i.e. transmission ellipsometry) or by oblique reflection from its specular surface (i.e. reflection ellipsometry). The original and widest usage of the term ellipsometry, however, is to describe the reflection experiment performed to obtain the optical properties of specular surfaces, the optical properties and thicknesses of thin films, and the nature of specular interfaces. Transmission ellipsometry is used for analysis of molecular structure through natural anisotropy, however, this experiment is most often identified, not as ellipsometry, but in terms of the specific information extracted such as optical rotation or circular dichroism.

The most general polarization state of a light beam is specified by the Stokes parameters.¹ These four parameters describe (i) the irradiance (or power flux) \( I \) in the beam, (ii) the elliptical polarization state of the beam, characterized by the tilt angle \( Q (-90^\circ < Q \leq 90^\circ) \) and the ellipticity \( e \ (-1 \leq e \leq 1) \), which is the ratio of the length of the minor axis to that of the major axis of the ellipse, and (iii) the degree of polarization \( p (0 \leq p \leq 1) \). Measurement of the incident and reflected irradiances \( I_I \) and \( I_r \), respectively, yields the reflectance \( R = I_r/I_i \) of the sample in a measurement called reflectometry. This is distinct from the ellipsometry measurement, which involves measurement of \( (Q_i, e_i) \) and \( (Q_r, e_r) \) for the incident and reflected beams. In some instruments, reflectometry and ellipsometry are performed simultaneously; then the measurement is sometimes called three-parameter ellipsometry.² Other instruments provide \( Q, e \), and \( p \) of the reflected beam, a capability that is important when the sample depolarizes the incident beam. This measurement is often called polarimetry. In standard reflection ellipsometry on a uniform isotropic sample, rather than expressing the outcome in terms of the beam parameters \( Q \) and \( e \), it is conventional to use the sample parameters \( \psi \) and \( \Delta \), where \( \tan \psi \exp(i\Delta) = r_p/r_s \). In this expression, \( r_p \) and \( r_s \) are the complex amplitude reflection coefficients of the reflecting sample for \( p \) and \( s \) linear polarization states in which the electric field vibrates parallel (\( p \)) and perpendicular (\( s \)) to the plane of incidence.

Because two data values \( \psi \) and \( \Delta \) are determined in a standard ellipsometry experiment, a measurement at one wavelength can provide two sample parameters.³ For example, for a sample consisting of an atomically smooth film-free material, the complex index of refraction \( N \) of the material can be obtained at the wavelength \( \lambda \) of the incident beam. \( N \) provides a complete description
of the linear optical properties of an isotropic material and includes its real part the real index of refraction \( n \) and as its imaginary part the extinction coefficient \( k \), i.e. \( N = n - ik \). For a sample consisting of a transparent film (i.e. \( k = 0 \)) on a substrate of known complex index of refraction, \( n \) of the film and its thickness \( d \) can be determined within limitations. In contrast to ellipsometry, only one data value \( R \) is determined in a reflectometry experiment. Hence, reflectometry at selected \( \lambda \) on a film-free material cannot provide \( N \). As a result, ellipsometry is the preferred method for measuring \( N \) for \( \lambda \) within the range of conventional ellipsometers, from the ultraviolet (200–300 nm) to the near-infrared (800 nm), for strongly absorbing materials, e.g. metals and semiconductors, and for weakly absorbing materials that exist only in thin film form. One limitation of ellipsometry is its inability to measure low \( k \) values or low absorption coefficients \( \alpha \), where \( \alpha = 4\pi k/\lambda \). Typical ellipsometers are limited by accuracy to \( \alpha > 10^2 \text{ cm}^{-1} \). This is in contrast to transmission spectroscopy in which the ratio of the transmitted to incident irradiance is determined, and the sample thickness may be increased to measure low \( \alpha \) values.

The term ellipsometry was coined by Rothen in 1944, and the precursor of present day instruments was developed soon after when the photomultiplier tube (PMT) became available.\(^3\) The primary limitation of early manually operated instruments was the time taken to perform one \((\Psi, \Delta)\) measurement, typically \(\sim 10\) min. Thus, the early instruments could be used only to study static or quasistatic samples. Upon introduction of laboratory computers for data collection and reduction, a number of automatic ellipsometers were invented, starting in the late 1960s.\(^4\) Design differences arose from the diverse methods used to generate and detect polarized light. A common feature of these automatic instruments is the \(10^3 - 10^6\) increase in measurement speed compared with the manual ellipsoid. As a result, two important capabilities emerged, RTE and SE. In RTE, measurements at fixed \( \lambda \) are performed versus time on dynamic samples, revealing the kinetics of film growth or materials and surface modification. In SE, measurements closely spaced versus \( \lambda \) are performed on static or quasistatic surfaces. The latter measurements yield the \( \lambda \)-dependence of the optical properties of the sample, allowing one access to a wealth of information including sample composition, crystallinity, microstructure, and temperature, providing that suitable databases exist. Recent advances have led to an expansion of the capabilities of automatic ellipsometers.\(^5\) For example, the measurement time for a 100-point spectrum from the ultraviolet to near-infrared has been reduced from \(\sim 15\) min for a conventional automatic spectroscopic ellipsometer to 16 ms for a multichannel ellipsometer with a photodiode array detector. The latter advance permits real time spectroscopy on dynamic surfaces.

The ellipsometers described in the previous paragraph were designed for selected wavelength or spectroscopic operation from the ultraviolet (200–300 nm) to the near-infrared (800 nm). The optical properties of materials over this range provide information on absorption and dispersion associated with electronic transitions between the valence and conduction bands.\(^5\) Thus, the density of electronic states within \(\sim \pm 5\) eV of the Fermi level can be probed. Parallel efforts have led to ellipsometers with broad-band infrared sources covering the range from 700 to 7000 cm\(^{-1}\).\(^6\) The optical properties over this range provide information on the chemical bonding of a variety of materials as well as the free electron characteristics of conductors and doped semiconductors. Finally, ellipsometers have also been developed to study materials outside the ultraviolet to mid-infrared range.\(^2\) These specialized instruments exploit synchrotron sources to cover (i) the far-infrared range from 20 to 800 cm\(^{-1}\) in studies of phonons and plasmons for superconductors, (ii) the vacuum ultraviolet from 50 to 200 nm in studies of the energy band structures of wide gap materials, and (iii) the extreme ultraviolet, \(\sim 10\) nm in studies of core electronic levels.

In conventional reflection ellipsometry, the surface is probed with a collimated 1–5 mm diameter beam at an angle of incidence of 50–75°.\(^1\) Thus, the physical parameters of the sample must be uniform over the probed area if the \((\Psi, \Delta)\) data are to be readily interpretable using simple optical models. However, samples are often not perfect over the full beam area. In comparison to reflectometry, however, ellipsometry provides greater immunity to localized surface defects that scatter light out of the specular beam. However, if the sample is very rough or inhomogeneous with a correlation length of the structure greater than \(\sim 10\) nm, then conventional ellipsometry may fail due to light scattering that can depolarize the beam \((p < 1)\) and lead to unmanageable complexities in data analysis. If the correlation length of the inhomogeneity is greater than \(\sim 10\), then IE or microellipsometry (ME) can be applied to characterize the sample.\(^2\) In IE, a two-dimensional charge-coupled device (CCD) is used as a detector to collect images in \((\Psi, \Delta)\) over a spot size of \(\sim 3\) mm with a resolution of 10 µm. In ME, a spot size of \(\sim 10\) µm is scanned over the sample surface to collect images in \((\Psi, \Delta)\). Because of its sensitivity to relative phase changes, ellipsometry is more strongly affected than reflectometry by surface layers such as oxides that are sometimes neglected in data interpretation. Thus, the problem of obtaining accurate optical properties of materials by ellipsometry becomes one of preparing atomically clean smooth surfaces.
The popularity of ellipsometry arises from numerous applications that rely on its high surface sensitivity and its ability to probe samples in situ and in real time in varied environments.\textsuperscript{1-7} Because of the high sensitivity to changes in the relative phases of the orthogonal p and s polarization components of the beam, through the parameter $\Delta$, ellipsometry can detect changes in the average thickness of surface layers equivalent to 0.01 monolayer. Importantly, this level of sensitivity is possible for samples immersed in any medium that is transparent to the beam. First, ellipsometry can be used to characterize thin films, surfaces, interfaces and bulk solids prepared and processed in ultrahigh vacuum (UHV). It can also be used to probe processes occurring in various levels of vacuum or controlled gaseous environments, including physical and chemical adsorption, oxidation, annealing and crystallization, physical and chemical vapor deposition, and plasma etching. Finally, ellipsometry can also be applied to study processes occurring in laboratory ambients as well as in liquids. Such applications are in the field of electrochemistry, including ionic adsorption, anodic oxidation, passivation, corrosion, electropolishing, and electrodeposition and in the fields of biochemistry and medicine, including coagulation, immunological reactions, and cell surface characterization. Thus, ellipsometry has been used widely by chemists and physicists, by materials, electrical, and chemical engineers, and by biochemical and medical researchers.

2 HISTORY

The first studies in ellipsometry are credited to Paul Drude, although the measurement technique was not called ellipsometry until 1944.\textsuperscript{3} As part of his dissertation research performed at Gottingen University and published from 1887 to 1890, Drude developed the first theory describing reflection and refraction of light at the surfaces of absorbing solids.\textsuperscript{8-12} In attempts to test the theory experimentally, Drude found that the polarization state of light reflected from the surface of an optically absorbing crystal changed gradually with time after it was cleaved in air.\textsuperscript{9} This change was attributed to oxidation of the surface, and Drude was able to relate quantitatively the observed polarization change to the complex index of refraction $N$ of the crystal and the optical thickness ($nd$) of the oxide layer. In doing so, Drude utilized the parameters ($\psi$, $\Delta$) to characterize reflection from the surface, and, applying Maxwell’s equations, he derived expressions for ($\psi$, $\Delta$) for the single-layer model (see section 3.3) consisting of an oxide on the crystal surface.\textsuperscript{10,11} Drude also developed first order expansions of these expressions in ($d/\lambda$), valid for very thin films ($d < 1 \text{ nm}$). Having identified the origin of the changes in polarization with time, Drude measured $N$ for several metals.\textsuperscript{12} His results are remarkably close in many cases to modern values.\textsuperscript{13}

In Drude’s study of the oxidation of crystals, he was unable to verify independently that the deduced thicknesses were correct. Much later in 1935, Leif Tronstad at the Norwegian Institute of Technology in Trondheim measured the thicknesses of monolayers of fatty acids on mercury surfaces using Drude’s method and the first order expansions of the single layer expressions.\textsuperscript{14} The thicknesses were found to be in accord with molecular models for the monolayer. Tronstad also performed pioneering studies of film formation on electrically biased metal surfaces immersed in solution.\textsuperscript{15} In the early instruments, the polarization state of the reflected beam was determined through tedious visual observations and much effort was devoted to simplifying this process.

In 1944, Rothen first coined the term ellipsometer to describe an instrument that he developed to measure the thicknesses of protein films on slides.\textsuperscript{5,16} In the instrument of Rothen (see Figure 1), incident monochromatic light was polarized by a polarizer with its transmission axis set at a known tilt angle $P$, measured with respect to the plane of incidence. The beam was reflected from a Cr-coated glass slide which was in turn coated with barium stearate monolayers. One-half of the illuminated area was covered by a single monolayer while the other half was covered by three monolayers. This generated an 4.8 nm step at the center of the viewing area. Thus, the reflected beam was elliptically polarized with the major axes of the ellipses from the two halves forming a 3° angle for optimal viewing. This reflected beam was analyzed first with a quarterwave retarder and then with a second polarizer (called the analyzer). The retarder imposes a 90° phase shift between the electric field components along orthogonal axes of the device, designated the fast (F) and slow (S) axes. When the retarder was oriented so that the fast axis bisected the angle formed between the major axes of the two ellipses, then the output of the waveplate consisted of two nearly linear polarization states with small right and left ellipticities for the two halves of the beam. In this situation, the analyzer was set such that if one looked through it at the sample, one saw a weak light output (nearly “null”) of equal irradiances in the two halves of the beam. Finally, the film to be studied was added to the stearate-coated slide. This led to a brightening of one half of the beam and a dimming of the other half. By measuring the angle by which the analyzer had to be rotated to equalize the irradiance, the film thickness could be calculated. Since this rotation angle could be determined to within $\pm 0.01^\circ$, a change in thickness of 0.01 nm over the surface of the slide could...
be detected. Rothen used such an instrument to follow immunological reactions.

The sequence of optical elements in Rothen’s ellipsometer is identical to that used in today’s state-of-the-art photometric ellipsometers. The cumbersome half-shade detection, however, that relied on Langmuir–Blodgett film deposition methods, became obsolete soon after the development of the PMT in the late 1940s. With the PMT used as a detector in place of the eye, the instrument configuration of Rothen shown in Figure 1 was adapted as one variant of the popular null ellipsometer. In this case special substrates were not needed, and the polarizer and analyzer were rotated alternately to reach a null PMT output. The thickness and optical properties of the film were determined from the angular settings of the optical components at null (see section 4.1.1). In the 1950s and 1960s efforts were initiated to develop automatic “recording” ellipsometers that could collect \( \psi, \Delta \) at sufficiently high speed to follow the kinetics film growth in real time. These RTE efforts were motivated by the introduction of the first laboratory computers that could be used for instrument control, repetitive data collection, and data reduction. By 1969, several automatic ellipsometer designs based on null (or compensating) principles and on photometric principles had been developed, as described in section 4.1. Starting in 1984, more advanced instruments were developed along the same basic principles but incorporating either rapid scanning sources or detection systems so that SE could be performed on dynamic surfaces in real time. Such instruments for RTSE are continuing to be improved to this date.

The advancement of the instruments and applications for ellipsometry can be appreciated by consulting the series of seven proceedings of conferences devoted to ellipsometry. The first conference was held in 1963 in Washington DC, USA, and the most recent one as of this writing was held in 1997 in Charleston SC, USA.

### 3 MEASUREMENT PRINCIPLES

The theoretical basis for the ellipsometry measurement is given here. First, the electric field associated with polarized light will be described, and the optical properties of isotropic media will be defined. Then, the reflection of light from (i) a film-free isotropic material, (ii) a single-layer structure consisting of an isotropic ambient medium, a thin film, and a semi-infinite substrate, and finally, (iii) an \( m \)-layer structure consisting of \( m \) isotropic thin films between the ambient medium and substrate will be treated in detail. Treatments of the more difficult problem of anisotropic component materials can be found in Azzam and Bashara and Collins et al.
3.1 Polarization and the Optical Properties of Materials

The electric field, \( \mathbf{E} \), associated with a polarized monochromatic or quasimonochromatic light wave propagating along \( \mathbf{z} \) in an isotropic medium is given by Equations (1) and (2):\(^{1,23} \)

\[
\mathbf{E}(\mathbf{r}, t) = (E_{0x}\mathbf{x} + E_{0y}\mathbf{y}) \exp \left\{ i\omega \left( t - \frac{Nz}{c} \right) \right\} (1)
\]

\[
= (E_{0x}\mathbf{x} + E_{0y}\mathbf{y}) \exp \left\{ i\omega \left( t - \frac{nz}{c} \right) \right\} \times \exp \left\{ \frac{-w k z}{c} \right\} (2)
\]

where \( E_{0x} \) and \( E_{0y} \) are defined by Equations (3) and (4):

\[
E_{0x} = |E_{0x}| \exp(i\delta_x) \quad (3)
\]

\[
E_{0y} = |E_{0y}| \exp(i\delta_y) \quad (4)
\]

These expressions follow the sign convention used most widely by the optics and ellipsometry communities. In Equations (1–4), \( \omega \) is the angular frequency of the light wave, \( c \) is the speed of light in vacuum, and \( E_{0x} \) and \( E_{0y} \) are the complex electric field amplitudes along the orthogonal \( x \) and \( y \) directions whose ratio specifies the polarization. In addition, \( N = n - ik \) is the complex index of refraction, where \( n \) is the (real) index of refraction and \( k \) is the extinction coefficient.

The polarization state of the plane wave of Equations (1–4) can be described in terms of the complex field amplitudes.\(^{24}\) By defining Equations (5) and (6):

\[
\tan \gamma = \frac{|E_{0y}|}{|E_{0x}|} \quad (5)
\]

\[
\delta = \delta_y - \delta_x \quad (6)
\]

then the ellipticity angle \( \chi = \tan^{-1} e (\LAMBDA - 45^\circ \leq \chi \leq 45^\circ) \) and the tilt angle \( Q (\LAMBDA - 90^\circ \leq Q \leq 90^\circ) \) associated with the ellipse of polarization are given by Equations (7) and (8):

\[
\sin 2\chi = -\sin 2\gamma \sin \delta \quad (7)
\]

\[
\tan 2Q = -\tan 2\gamma \cos \delta \quad (8)
\]

Within the convention used here, positive values of \( \chi \) and \( e \) denote right-handed polarization states (clockwise rotation of \( E \) at a fixed point in space looking toward the source); negative values denote left-handed polarization states.

The index of refraction \( n \) describes the factor by which the speed of the wave in the medium is reduced relative to the speed in vacuum.\(^{23}\) Thus, \( v_p = c/n \), where \( v_p \) is the speed of the planes of constant phase for the wave of Equations (1–4). The extinction coefficient \( k \) describes the exponential rate at which the electric field decays within the medium due to dissipative absorption. In fact, the absorption coefficient \( \alpha \) of the medium is given by Equation (9):

\[
\alpha = \frac{4\pi k}{\lambda} \quad (9)
\]

\( \alpha \) describes the exponential attenuation of the irradiance \( I \) with distance \( z \) that the wave travels, according to \( I = I_0 \exp(-\alpha z) \). An alternative approach for describing the optical properties is the dielectric function, \( \varepsilon = \varepsilon_1 - i\varepsilon_2 = N^2 \), where \( \varepsilon_1 \) and \( \varepsilon_2 \) are the real and imaginary parts. The two descriptions of the optical properties are related through Equations (10–13):

\[
\varepsilon_1 = n^2 - k^2 \quad (10)
\]

\[
\varepsilon_2 = 2nk \quad (11)
\]

\[
n = \left\{ \frac{\varepsilon_1 + (\varepsilon_1^2 + \varepsilon_2^2)^{1/2}}{2} \right\}^{1/2} \quad (12)
\]

\[
k = \left\{ \frac{-\varepsilon_1 + (\varepsilon_1^2 + \varepsilon_2^2)^{1/2}}{2} \right\}^{1/2} \quad (13)
\]

Finally, it should be mentioned that for an anisotropic material, \( \varepsilon \) is no longer orthogonal to the propagation direction, \( \mathbf{z} \). In addition, \( \varepsilon \) is a second-rank tensor, and there exist two values of \( N \) appropriate when the displacement, \( \mathbf{D} = \varepsilon \mathbf{E} \), is along two mutually orthogonal directions.\(^{23}\)

3.2 Ellipsometry Measurement of a Single Interface

In describing the reflection of a polarized, monochromatic light wave from an ideal specular interface between two isotropic media, the electric field vectors of the incident (i) and reflected (r) waves are resolved along the orthogonal \( p \) and \( s \) directions, which are parallel (p) and perpendicular (s) to the plane of incidence. This yields the pairs of components \( (E_{00p})_i \) and \( (E_{00s})_i \) for the incident wave, and \( (E_{00p})_r \) and \( (E_{00s})_r \) for the reflected wave (assuming no depolarization). The plane of incidence contains both incident and reflected wave propagation vectors (see Figure 2), the latter being normal to the planes of constant phase for the two waves. In the reflection process, the key parameters that characterize the interface are the complex amplitude reflection coefficients, \( r_p \) and \( r_s \). These coefficients are defined separately for the \( p \)- and \( s \)-directions as the ratio of reflected and incident electric field components by Equations (14–17):\(^5\)

\[
r_p = |r_p| \exp(i\delta_p) = \frac{(E_{00p})_r}{(E_{00p})_i} \quad (14)
\]

\[
= \frac{\varepsilon_i N_{i\perp} - \varepsilon_s N_{i\perp}}{\varepsilon_i N_{i\perp} + \varepsilon_s N_{i\perp}} \quad (15)
\]
Electric field vectors resolved into p and s components, shown in the positive sense, for light beams incident (i), reflected (r), and transmitted (t) at an interface between an ambient and a substrate. The propagation vectors for the beams are labeled $k_i$, $k_r$, and $k_t$.

$$r_s = |r_s| \exp(i\delta_s) \equiv \frac{E_{0s}}{E_{is}}$$

$$= \frac{N_{a\perp} - N_{e\perp}}{N_{a\perp} + N_{e\perp}}$$

where

$$N_{a\perp} = N_a \cos \phi_i$$

$$N_{e\perp} = N_a \cos \phi_i = (\varepsilon_a - \varepsilon_s \sin^2 \phi_i)^{1/2}$$

$N_a = n_a - i k_a$ and $N_i = n_i - i k_i$ are the complex indices of refraction of the media containing the incident wave (a, ambient) and the transmitted wave (s, substrate), respectively, and $\varepsilon_a$ and $\varepsilon_s$ are the dielectric functions. $\phi_i$ and $\phi_f$ are the angles of incidence and transmission (see Figure 2), related by Snell’s law. In Equations (14) and (16), $\delta_p$ and $\delta_s$ are the phase changes that occur upon reflection, and $|r_p|$ and $|r_s|$ are the ratios of the amplitudes for the complex fields associated with the reflected and incident waves. Figure 2 depicts positive sign conventions for the p and s electric field components. The different phase and amplitude changes for the p and s components lead to a change in the polarization state of the wave upon reflection, and it is this change that is measured by ellipsometry. Equations (14) and (16) can be applied to surfaces with multiple interfaces whereas Equations (15) and (17–19) are valid only for a single interface.

Assuming no depolarization by the sample, the polarization states of the incident and reflected waves are specified by the complex ratios $[(E_{0p}/E_{0s})]$ and $[(E_{0r}/E_{0i})]$, respectively.1 In ellipsometry, the change in polarization state upon reflection is measured as a ratio of reflected and incident polarization states. Thus, for a single interface between isotropic media, the object of conventional reflection ellipsometry is $\rho$, the complex amplitude reflection ratio given by Equations (20–22):5

$$\rho = \frac{r_p}{r_s} = \frac{(E_{0p}/E_{0s})}{(E_{0r}/E_{0i})} = \left|\frac{r_p}{r_s}\right| \exp[i(\delta_p - \delta_s)]$$

$$= \tan \psi \exp(i\Delta)$$

$$= \sin^2 \phi_i \left[ (\varepsilon_s/\varepsilon_a) - \sin^2 \phi_i \right]^{1/2} \cos \phi_i$$

$$\sin^2 \phi_i + \left[ (\varepsilon_s/\varepsilon_a) - \sin^2 \phi_i \right]^{1/2} \cos \phi_i$$

Here $\psi$ and $\Delta$ are the ellipsometry angles that are commonly used to represent the interaction of the incident wave with the reflecting interface. Although Equations (20) and (21) can be applied to isotropic surfaces having any number of interfaces, Equation (22) is valid for a single interface only.

When one or both media are anisotropic, incident electric field components in either the p or s directions lead to components of the reflected wave in both directions. Thus, in general, four complex amplitude reflection coefficients, $r_{pp}$, $r_{ps}$, $r_{sp}$, and $r_{ss}$, can characterize reflection at such an interface.1 Ellipsometric measurements for different incident polarization states, angles of incidence, or surface orientations can yield the three complex amplitude reflection ratios.25

The simplest system measurable by reflection ellipsometry is the ideal interface between two media. An example is an opaque substrate that presents to the ambient an atomically smooth abrupt termination of the bulk structure. Real systems inevitably deviate from this mathematical idealization owing to the presence of surface roughness and/or native oxide or other contaminant layers. Even if atomically smooth clean surfaces could be generated and measured in situ under UHV, surface reconstruction reorders the top monolayer or more, resulting in a measurable difference in the optical response of the monolayer(s) compared with the bulk. Ignoring such problems for the moment, the dielectric function of the substrate $\varepsilon_s$ can be deduced from $\psi$ and $\Delta$ if the dielectric function of the ambient $\varepsilon_a$ and angle of incidence $\phi_i$ are known (Equation 23):5

$$\varepsilon_s = \varepsilon_a \sin^2 \phi_i \left\{ 1 + \tan^2 \psi \frac{(1 - \rho)^2}{(1 + \rho)^2} \right\}$$

For a two-medium structure with $|\varepsilon_s/\varepsilon_a| \geq 1$, $\psi$ and $\Delta$ are constrained to $0^\circ \leq \psi \leq 45^\circ$ and $0^\circ \leq \Delta \leq 180^\circ$, within the sign convention adopted here. The right side of Equation (23) is often applied to experimental data in $\rho$ when no effort has been taken to ensure that the sample is a two-medium structure. The left side is then called the pseudodielectric function, written as $\langle \varepsilon \rangle = \langle \varepsilon_s \rangle - i \langle \varepsilon_2 \rangle$. $\langle \varepsilon \rangle$ is even used for samples known to consist of multiple layers. In this case, $\langle \varepsilon \rangle$ provides an alternative to $(\psi, \Delta)$ for describing interaction of the incident beam with
the surface, but does not convey any direct physical information.

Two angles of incidence are of interest in the ellipsometry experiment for a single interface. The first is the pseudo-Brewster angle \( \phi_B \) at which \( \tan \psi \) and the p-component reflectance \( |r_p| \) are minimized. This angle is identical to the Brewster angle \( \phi_B = \tan^{-1}(n_s/n_a) \) when \( k_s = k_a = 0 \). The second angle of incidence of interest is the principal angle \( \phi_p \) at which \( \Delta = 90^\circ \). The principal angle is usually within \( \sim 1^\circ \) of the pseudo-Brewster angle for absorbing materials and is equal to it for transparent materials. The relative uncertainty in \( \epsilon_s \), \( \delta \epsilon_s/\epsilon_s \), owing to uncertainties \( \psi \) and \( \Delta \) is minimized at \( \phi_p \). For this reason, if one is interested in measuring the dielectric function \( \epsilon_s \) of a material, then the ellipsometer should be operated with \( \phi_i = \phi_p \). Under these optimum conditions, experimental fluctuations of \( \psi \cong 0.001^\circ \) and \( \delta \Delta \cong 0.002^\circ \), achievable with an automatic ellipsometer, lead to relative uncertainties in \( \epsilon_s \) of \( 1 \times 10^{-4} \). In section 3.3, it will be shown that sample surface preparation, not ellipsometer precision, limits the ability to deduce \( \epsilon_s \) accurately. Precision is paramount, however, if SE data are to be differentiated with respect to the photon energy in order to characterize the composition or temperature of a crystalline solid based on the positions of the critical points in the electronic density of states (see section 5.3).

### 3.3 Ellipsometry Measurement of a One-layer Structure

The \( p \) and \( s \) complex amplitude reflection coefficients, defined as the ratio of the reflected and incident electric field components in the \( p \) and \( s \) directions, can also be used to characterize a system consisting of two or more interfaces. For a one-layer sample consisting of two ideal atomically smooth and abrupt interfaces and three different media (ambient/film/substrate), the reflection coefficients denoted \( r_{p2} \) and \( r_{s2} \) are given by:  

\[
\begin{align*}
    r_{p2} &= \frac{r_{p,af} + r_{p,fs}Z_f}{1 + r_{p,af}r_{p,fs}Z_f} \quad (24) \\
    r_{s2} &= \frac{r_{s,af} + r_{s,fs}Z_f}{1 + r_{s,af}r_{s,fs}Z_f} \quad (25)
\end{align*}
\]

where  

\[
Z_f = \exp \left\{ \frac{4 \pi id}{\lambda} (\epsilon_i - \epsilon_a \sin^2 \phi_i)^{1/2} \right\} \quad (26)
\]

The ellipsometry angles for the one-layer sample are expressed as:  

\[
r_2 = \frac{r_{p2}}{r_{s2}} = \tan \psi \exp(i\Delta) \quad (27)
\]

In Equations (24–26), \( \{r_{p,af}, r_{s,af}\} \) and \( \{r_{p,fs}, r_{s,fs}\} \) are the \( p \) and \( s \) reflection coefficients for the ambient/film (af) and film/substrate (fs) interfaces, obtained through expressions analogous to Equations (15) and (17–19). In addition, \( \epsilon_i = \epsilon_{1f} - \epsilon_{2f}, \) \( d_i, \) and \( \lambda, \) are the dielectric function of the film, the thickness of the film, and the wavelength of the incident light, respectively.

The basic data analysis problem in the characterization of thin films by ellipsometry involves determining \( \epsilon_{1f}, \) \( \epsilon_{2f}, \) and \( d_i \) from the measured \((\psi, \Delta)\) values using the presumed known values of \( \epsilon_a, \epsilon_s, \phi_i, \) and \( \lambda. \) Because three thin film parameters cannot be uniquely deduced from only two measured interaction parameters, multiple measurements of \((\psi, \Delta)\) are needed. These can be obtained at different \( \lambda \) or \( \phi_i, \) or under certain limitations for different ambients, substrates, or film thicknesses. One of these limitations requires that \( \epsilon_i \) does not depend on the ambient, substrate, or thickness. Even for the simpler case of a nonabsorbing film with \( \epsilon_{2f} = 0, \) Equations (24–27) cannot be inverted to provide a unique solution for \( d_i \) from a single measurement of \((\psi, \Delta)\). The periodicity of \( Z_f \) in Equation (26) shows that if \( d_{i,0} \) is the minimum solution, then Equation (28)  

\[
d_i = d_{i,0} + \frac{m\lambda}{2(\epsilon_i - \epsilon_a \sin^2 \phi_i)^{1/2}} \quad (28)
\]

also provides solutions for all integers \( m \geq 1. \) In addition, as there are no closed-form expressions for either \( \epsilon_{1f} \) or \( d_{i,0}, \) determining these parameters from \((\psi, \Delta)\) often involves Newton’s method of numerical inversion, although more efficient algorithms are also available. For a transparent film, \((\psi, \Delta)\) values at two wavelengths, \( \lambda_0 \) and \( \lambda_1, \) can be inverted to obtain \( \epsilon_{1f}(\lambda_0) \) and \( \epsilon_{1f}(\lambda_1) \) and two families of solutions for \( d_i. \) The correct \( d_i \) is the value common to the two families. This approach has entrenched ellipsometry as the method of choice for determination of thickness and index of refraction of dielectrics on semiconductors for use in microelectronics technology.

For semiconductor films that are nonabsorbing at \( \lambda_0 \) and \( \lambda_1, \) corresponding to photon energies \( E_0 = hc/\lambda_0 \) and \( E_1 = hc/\lambda_1 \) below the band gap, and absorbing at \( \lambda_2, \) with \( E_2 = hc/\lambda_2 \) above the gap, the approach of the previous paragraph can be used to deduce \( \epsilon_{1f}(\lambda_0), \) \( \epsilon_{1f}(\lambda_1), \) and \( d_i \) from \((\psi, \Delta)\) at \( \lambda_0 \) and \( \lambda_1. \) Then, numerical inversion can be applied to deduce \( \epsilon_{1f}(\lambda_2) \) and \( \epsilon_{2f}(\lambda_2) \) from \((\psi, \Delta)\) at \( \lambda_2, \) using the known value of \( d_i. \) Thus, a light source with the ability to vary \( \lambda \) is a benefit for the analysis of discrete data. Other approaches for solving the one-layer problem with discrete data on absorbing films involve measurements at multiple incidence angles \((1, 26)\) and combined ellipsometry and reflectance. In fact, the most successful method for characterizing absorbing
ELLIPTOSCOPY IN ANALYSIS OF SURFACES AND THIN FILMS

films is with SE.\(^{(5)}\) SE provides an additional advantage in that \(\epsilon_1\) is obtained as a continuous function of \(\lambda\). More advanced analysis techniques for nonabsorbing and absorbing films that exploit SE and RTSE data will be described in sections 4.5 and 5.2.

The complex amplitude reflection ratio of Equation (27) can be expressed as a power series in \(d_m\), and for \(d_k\) less than about 1 nm all terms beyond first order can be neglected as described by Equation (29):\(^{(5)}\)

\[
\rho_2 \approx \rho \left\{ 1 + \frac{4\pi d_m \cos \phi_1}{\lambda} \right\} \times \frac{\epsilon_s(\epsilon_1 - \epsilon_a)(\epsilon_s - \epsilon_1)}{\epsilon_1(\epsilon_s - \epsilon_a)(\epsilon_s \cot^2 \phi_1 - \epsilon_a)}
\]  

(29)

Here \(\rho\) is the bare substrate amplitude reflection ratio from Equation (22). The result of Equation (29) shows that fluctuations of \(\delta \psi \cong 0.001^\circ\) and \(\delta \Delta \cong 0.002^\circ\) achievable with automatic instruments correspond to \(\delta d_1 \cong 0.001\) nm. Thus, minute changes in monolayer coverage of a surface can be detected with an automatic ellipsometer. This demonstrates that the sample surface condition rather than the ellipsometer precision is a controlling factor in the accurate determination of \(\rho\) and thus \(\epsilon_s\). Equation (29) also demonstrates, for ultrathin dielectric film formation on a dielectric substrate, that \(\psi\) remains constant and only \(\Delta\) changes. Thus, a single interaction parameter is obtained and it is impossible to deduce both \(\epsilon_{1f}\) and \(d_f\).

3.4 Ellipsometry Measurement of a Multilayer Structure

The analogs of Equations (14–19) can be derived for an \(m\)-layer system using matrix methods to perform the required manipulations.\(^{(1,28)}\) The sample structure is shown in Figure 3. The method consists of determining the 2 \(\times\) 2 scattering matrix \(S_j\) (\(v\) designating either \(p\) or \(s\)) as a product of \((m + 1)\) interface matrices \(I_{v,j,(j+1)}\) \((j = 0, \ldots, m)\) and \(m\) layer matrices \(L_j\) \((j = 1, \ldots, m)\), according to Equation (30)

\[
S_{v,(m+1)} = I_{v,01}L_1I_{v,12}L_2 \cdots L_jI_{v,j,(j+1)}L_{j+1} \cdots L_mI_{v,m,(m+1)}
\]  

(30)

Here the subscript “0” designates the ambient medium from which the light wave is incident and “\(m + 1\)” designates the substrate medium. The two matrices are given by Equations (31) and (32):

\[
I_{v,j,(j+1)} = \frac{1}{t_{v,j,(j+1)}} 1 \quad r_{v,j,(j+1)}
\]

\[
L_j = \begin{bmatrix} Z_j & 0 \\ 0 & Z_j^{-1} \end{bmatrix}
\]  

(31)

(32)

Figure 3 Schematic diagram of an \(m\)-layer structure. \(N_{v}\), \(N_{j}\), and \(N_{m}\) are the complex indices of refraction for the ambient, the \(j\)th layer of thickness \(d_j\), and the substrate, respectively. \(\phi_{j}\) is \(\phi_0\) the angle of incidence on the first layer and \(\phi_{j}\) is the angle of incidence at the interface between the \(j\)th and \((j + 1)\)st layers.

Here \(r_{v,j,(j+1)}\) and \(t_{v,j,(j+1)}\) are the amplitude reflection and transmission coefficients for the single interface between media \(j\) and \(j + 1\), respectively. The transmission coefficients are defined in the same way as the reflection coefficients, but as the ratio of transmitted and incident electric field components across one or more interface (see Equations 14 and 16). For the specific case of a single interface between media \(j\) and \(j + 1\), these coefficients are given by Equations (33) and (34)

\[
t_{p,j,(j+1)} = \frac{2N_jN_{j+1}N_{j,j}}{\epsilon_{j+1}N_{j,j} + \epsilon_{j}N_{j+1,j}}
\]  

(33)

\[
t_{e,j,(j+1)} = \frac{2N_{j,j}\epsilon_{j+1}}{N_{j,j} + N_{j+1,j}}
\]  

(34)
Equations (35) and (36) where \( N_{j,\perp} \) and \( N_{j+1,\perp} \) are given by

\[
N_{j,\perp} = N_j \cos \phi_j \\
N_{j+1,\perp} = N_{j+1} \cos \phi_{j+1} = (\varepsilon_{j+1} - \varepsilon_j \sin^2 \phi_j)^{1/2}
\]

The angle of incidence for the interface between media \( j \) and \( j+1 \), denoted \( \phi_i \), is obtained from \( \phi_i \equiv \phi_0 \) through successive application of Snell’s law, Equation (37):

\[
N_0 \sin \phi_0 = N_1 \sin \phi_1 = \cdots = N_j \sin \phi_j = N_{j+1} \sin \phi_{j+1} = \cdots = N_m \sin \phi_m = N_{m+1} \sin \phi_{m+1}
\]

Finally, the parameter \( Z_j \) for the \( j \)th layer is given by Equation (38)

\[
Z_j = \exp \left\{ \frac{2 \pi i d_j}{\lambda} N_{j,\perp} \right\}
\]

where \( d_j \) is the thickness of layer \( j \). Once the scattering matrix is determined, then the complex amplitude reflection coefficients, \( r_{p,(m+1)} \) and \( r_{s,(m+1)} \), and \((\psi, \Delta)\) can be determined from Equations (39–41):

\[
r_{p,(m+1)} = \frac{[S_{p,(m+1)}]_{21}}{[S_{p,(m+1)}]_{11}}
\]

\[
r_{s,(m+1)} = \frac{[S_{s,(m+1)}]_{21}}{[S_{s,(m+1)}]_{11}}
\]

\[
\rho_{m+1} = \frac{r_{p,(m+1)}}{r_{s,(m+1)}} = \tan \psi \exp(i\Delta)
\]

Such computations are performed by computer from input values of \( \lambda, \phi_0, \{N_0, \ldots, N_m\} \), and \( \{d_1, \ldots, d_m\} \). The matrix equations can sometimes be inverted numerically to deduce one unknown complex index and one or more thicknesses if all other parameters are known. To deal with problems of this nature continuous SE data are required at least. If the unknown complex index can be expressed in terms of \( \lambda \)-independent parameters, then least squares regression analysis can be applied as will be described in section 4.5.

### 4 STATIC MEASUREMENT APPLICATIONS

Ellipsometry applications fall into two broad categories, namely, those in which measurements on a static sample yield its properties in a single stable state and those in which measurements on a dynamic sample surface yield the time evolution of its properties. For the former applications, the static sample can be either inside a controlled environment used for sample preparation or removed from the environment (i.e. in situ or ex situ ellipsometry, respectively). For measurements of dynamic surfaces, the term “RTE” is often used. It is important to note that “in situ” does not necessarily imply “real time”; however, “real time” does imply “in situ”. In general, ellipsometry measurements requiring several seconds or less to determine the interaction parameters are compatible with real time applications, whereas those that require a minute or more are not. Because most ellipsometry experiments are now performed in a multiple-measurement mode, usually continuously versus wavelength (i.e. SE), the instrument designs optimized for measurements on static and dynamic surfaces are notably different. In the most common case of SE from the ultraviolet to near-infrared, measurements on static surfaces are performed wavelength-by-wavelength using a white light source and monochromator with a detection system consisting of a single PMT. In contrast, SE measurements on dynamic surfaces are best performed in parallel for a range of wavelengths simultaneously using a white-light source with a detection system consisting of a spectrograph and rapid scanning photodiode array. Because of these design differences, the discussion of instruments and applications is divided into two sections. In this section ellipsometry on static surfaces is described and in section 5 RTE and RTSE are described.

#### 4.1 Instrument Designs, Operation, and Performance

It is instructive to consider the generic ellipsometer configuration in two parts as shown in Figure 4. The polarization generator part consists of a light source, focusing optics, a monochromator, collimating optics, a polarizer, and a compensator. The polarizer passes the electric field component of the incident light wave that is aligned along a specific axis of the device called the transmission axis, whereas it removes the electric field component of the wave that is aligned along the orthogonal extinction axis. The transmission axis, extinction axis, and propagation direction of the wave form a right-handed coordinate system (see Figure 4). The polarizer is inserted into a mounting that allows it to be rotated about an axis parallel to the propagation direction.
angles are set at $t$ by adjusting the polarizer and analyzer angles from unity. The detected irradiance is to be deduced. The analyzer is also rotatable such that the change in polarization imparted by the sample allows the change in polarization detected by the analyzer is:

$$E \propto \sin(P - C) \cos A + \sin C \cos(P - C) \sin A$$

The sample is mounted between the polarization generator and polarization detector parts of the instrument. The polarization detector consists of a second polarizer called an analyzer and a light detector. This combination allows the change in polarization imparted by the sample to be deduced. The analyzer is also rotatable such that the angle of the transmission axis with respect to the plane of incidence is $A$. In this configuration, the field amplitude transmitted by the analyzer is:

$$E_{0A} = E_{0P} r_s r_t [\rho \cos C \cos(P - C) \cos A - \rho \rho_c \sin C \sin(P - C) \cos A + \rho_c \cos C \sin(P - C) \sin A]$$

The detected irradiance is calculated as $I = (1/2)|E_{0A}|^2$, where $\varepsilon_0$ is the free space permittivity. In Equation (42), $E_{0P}$ is the field amplitude at the polarizer output. The sample parameters $r_t$ and $\rho_c$ are given by Equations (16), (20), and (21), and the compensator parameters are given by Equation (43):

$$\rho_c = \frac{t_s}{t_f} = \frac{E_{0CS} E_{0PF}}{E_{0PS} E_{0CF}} = T_c \exp(\delta_C) = \exp(\delta_C)$$

$t_s$ and $t_f$ are the transmission coefficients for field components along the compensator slow and fast axes, which are defined as ratios of the transmitted component, $E_{0CF}$ ($j = F, S$) to the incident component, $E_{0PS}$ ($j = F, S$). Compensators can exhibit dichroism; thus $T_C$ can deviate from unity.

In null or compensating ellipsometry, $\rho$ is determined by adjusting the polarizer and analyzer angles $P$ and $A$ to obtain the condition $I = 0$. In photometric ellipsometry, $\rho$ is determined by measuring the time dependence of the detector irradiance $I(t)$ that results when one of the angles, $P, C, A$, or $\delta_C$ is continuously varied either linearly or sinusoidally with time. Equation (42) describes the ideal operation of the ellipsometer of Figure 4 for an isotropic reflecting surface. Calibration procedures specific to each type of instrument must be employed to determine corrections to the nominal scale values read from the device mountings (or the phases of the angular variations) for the polarizer, compensator, and analyzer. In addition, the compensator must also be calibrated to determine $\rho_c$ for all measurement wavelengths. For accurate operation, correction terms may need to be included in Equation (42) that account for imperfect optical elements. For example, polarizers and compensators may exhibit strain birefringence or optical activity, or the sample may be enclosed in an optical cell whose windows are slightly birefringent. Ellipsometer alignment is also important for achieving high accuracy. For proper alignment, the optic and rotational axes of the components on each of the source and detector sides of the instrument must all be coincident. The resulting axes on the two sides must lie in the plane of incidence and must intersect one another on the surface of the sample. The light beam should be well collimated and follow the path defined by the intersecting optical axes. The angle of incidence can be determined by autocollimation of reflections from the surfaces of a mettallized prism at the sample position.

### 4.1.1 Manual Null Ellipsometers

The manual null ellipsometer was the most popular instrument in the period from 1950 to 1970, before the widespread use of laboratory computers for instrument automation. The applications of this instrument today include (i) single wavelength measurement for determination of the thickness and index of refraction of a nonabsorbing layer on a substrate of known $N_i$ using a one-layer model, and (ii) assessment of the accuracy of photometric instruments by measurement of the same sample by photometric and four-zone null ellipsometry. For the manual null ellipsometer used in the configuration of Figure 4, the polarizer angle, $P$, is adjusted so that the elliptical polarization state generated by the compensator is converted back into a linear state by the sample. Then the condition, $I = 0$, can be achieved by adjustment of the analyzer angle, $A$. To achieve high precision, the polarizer and analyzer are alternately rotated for minimum detector signal until the null is reached. The sample characteristic $\rho$ is obtained in terms of the angles at null, $P_n$ and $A_n$, Equation (44):

$$\rho = -\tan A_n \tan C + \rho_c \tan(P_n - C)$$

$$\frac{1 - \rho_c \tan C \tan(P_n - C)}{\tan C + \rho_c \tan(P_n - C)}$$
Null ellipsometers are operated with a quarterwave compensator setting ($\delta_C = 90^\circ$). For an ideal compensator ($\phi_C = i$) with $C = 45^\circ$, either of two inequivalent polarizer and analyzer null settings, $(P_2, A_2)$ and $(P_4, A_4)$, can establish $(\psi, \Delta)$. The two nulls are designated “zone 2” and “zone 4” according to Equations (45–48):

$$\psi = A_2 \geq 0$$  \hspace{1cm} (45)
$$\Delta = 360^\circ m - 90^\circ - 2P_2; \ m = 0 \text{ for } -90^\circ < P_2 < 45^\circ;$$
$$m = 1 \text{ for } 45^\circ \leq P_2 < 90^\circ;$$  \hspace{1cm} (46)

$$\psi = -A_4 \geq 0$$  \hspace{1cm} (47)
$$\Delta = 360^\circ m + 90^\circ - 2P_4; \ m = 0 \text{ for } -45^\circ \leq P_4 < 90^\circ;$$
$$m = 1 \text{ for } -90^\circ < P_4 < -45^\circ.$$  \hspace{1cm} (48)

Zone 1 and zone 3 nulls, $(P_1, A_1)$ and $(P_3, A_3)$, are obtained from the zone 1 null through Equations (45) and (46), but with an overall sign reversal on the right side of Equation (46) for $\Delta$. $(\psi, \Delta)$ are obtained from the zone 3 null through Equations (47) and (48) with the analogous sign reversal. Equations (45–48) use the ranges $0^\circ \leq \psi \leq 90^\circ$ and $-180^\circ < \Delta < 180^\circ$, and equivalent nulls outside $-90^\circ < P < 90^\circ$ and $-90^\circ < A < 90^\circ$ are not considered.

Among different designs, the null ellipsometer can provide the highest accuracy, independent of the values of $(\psi, \Delta)$. When $(\psi, \Delta)$ are obtained as a four-zone average, they are free of errors owing to a variety of component and sample imperfections. In addition, the null measurements are influenced neither by detector nonlinearity, as are photometric measurements, nor by source polarization and detector polarization sensitivity. The technique of azimuth modulation, whereby the null angles, $(P_n, A_n)$, are determined by averaging angles of equal signal level on opposite sides of the null, has been applied to enhance the precision of the method. Under usual operating conditions with an Xe arc lamp source, the precision of the manual null ellipsometer caused by shot noise and detector fluctuations is estimated to be $2\psi = \delta \Delta = 0.01^\circ$, which is near the limit of the resolution of typical scales on the component mountings. The primary disadvantage of the manual null instrument is the inordinate amount of patience and time required for the measurement (~10 min for single zone $(\psi, \Delta)$ by azimuth modulation). This is not a major concern if a single measurement on a static surface is desired. More often, however, measurements at many wavelengths and/or angles of incidence or data on dynamic surfaces are desired, and automation is essential to reduce the effort and increase the speed.

4.1.2 Automatic Null Ellipsometers

The null ellipsometer can be automated by attaching stepping motors to the polarizer and analyzer angular drives, allowing alternate adjustment of the angles $P$ and $A$ under computer control. Azimuth modulation can provide an error signal that directs the controller to the null settings. In this way, the measurement time can be reduced to ~1 s. Azimuth modulation can also be performed with Faraday cells, which are placed just after the polarizer and just before the analyzer as shown in Figure 5. In a Faraday cell, a magnetic field $H$ is applied to a transparent core material parallel to the direction of propagation of a

![Figure 5](image_url)  
**Figure 5** Simplified schematic of the optical and electronic components for an automatic nulling ellipsometer that uses Faraday cells for modulation and compensation. Ellipsometry in Analysis of Surfaces and Thin Films

A linearly polarized beam that passes through the material. The electric field vector for this beam is rotated by an angle proportional to the magnetic field (i.e., $\Delta Q \propto H$). If the polarizer and analyzer Faraday cells are driven by ac currents at $w_p$ and $w_A$ and $|r_p| = |r_s| = 1$, then the detector irradiance near null can be written as:

$$I(t) \equiv I_0[(A - A_n)A_m \sin(w_A t + \delta_A) + (P - P_n) \times P_m \sin(w_p t + \delta_p)]$$  \hspace{1cm} (49)

In Equation (49), $P_m \sin(w_p t + \delta_p)$ and $A_m \sin(w_A t + \delta_A)$ represent the polarizer and analyzer azimuth modulations. The terms in $I(t)$ serve as error signals that can be detected and used to direct the system to null with stepping motors on the polarizer and analyzer. Higher speed and precision can be obtained using Faraday cells both for modulation and polarization rotation. The instrument in Figure 5 uses concentric windings driven by high frequency (10 kHz) modulation and low frequency (1 kHz) nulling currents, the latter providing angular readout. Nulling is obtained in about 1 ms, more than $10^5$ times faster than the manual instrument.\(^{31}\) The ultimate precision of automatic null ellipsometers that use Faraday cells is an order of magnitude better than the manual instruments, with $2\delta \psi \equiv \delta \Delta \equiv 0.001^\circ$, and higher than any other automatic instrument.\(^{35}\) Because the automatic instruments are generally not designed to measure nulls in multiple zones, the measurements are less accurate than four zone-averaged null measurements.

### 4.1.3 Rotating Element Ellipsometers

Rotating element ellipsometers are constructed so that either the polarizer, compensator, or analyzer is mechanically rotated at frequency $w$ about an axis coincident with the propagation direction of the beam.\(^{33,34}\) For the rotating analyzer and polarizer instruments, the compensator is optional. Owing to its polarization sensitivity, the monochromator is usually placed before the fixed polarizer in the rotating analyzer configuration (see Figure 6) and after the fixed analyzer in the rotating polarizer configuration. For both configurations, the detector irradiance obeys Equation (50):

$$I(t) = I_0[1 + \alpha \cos(2(w t + \varphi) + \beta \sin(2(w t + \varphi))]$$  \hspace{1cm} (50)

where $w t + \varphi$ represents the time dependence of the polarizer or analyzer angle, $\varphi$ is a phase angle determined in calibration, and $\alpha$ and $\beta$ are normalized $2w$ Fourier coefficients. The coefficients are deduced by Fourier analysis of the detector signal which is sampled, using the output of an encoder mounted on the rotating element as a trigger. For the rotating analyzer instrument with $C = 0^\circ$, $\alpha$ and $\beta$ are related to $\psi$ and $\Delta$ through Equations (51) and (52):

$$\tan \psi = \left(\frac{1 + \alpha}{1 - \alpha}\right)^{1/2} \tan P$$  \hspace{1cm} (51)

$$\cos(\Delta - \delta_C) = \frac{\beta}{(1 - \alpha^2)^{1/2}}$$  \hspace{1cm} (52)

Without the compensator, $\delta_C = 0$ in Equation (52). For the rotating polarizer instrument, $P$ in Equation (51) is replaced by $A$. For typical rotation rates $w/2\pi$ in the range of 10–100 Hz, a single measurement of ($\psi$, $\Delta$) can be obtained in 5–50 ms, i.e. from a single half rotation.

The advantage of the rotating polarizer and analyzer instruments is that in the absence of the compensator, the sample is the only $\lambda$-dependent element.\(^{34}\) Thus, it requires no calibrations versus $\lambda$ and can be designed for a wide spectral range. Because the instrument measures $\cos(\Delta - \delta_C)$, the sign of the cosine argument is indeterminate, and for samples with one or more layers where $-180^\circ < \Delta \leq 180^\circ$ the ambiguity must be resolved in data analysis. The precision of the instrument depends on the reflecting surface, with an optimum for the detection of circularly polarized light ($\alpha = \beta = 0$). A compensator...
is needed when $\Delta \approx 0^\circ$ or $\pm 180^\circ$ (e.g. bulk dielectrics) because of the poor sensitivity in measuring linear polarization. The theoretical precision of the rotating analyzer instrument is somewhat poorer than the modulated null instrument. Detector nonlinearity is one source of inaccuracy for rotating element ellipsometers. For the rotating polarizer instrument the source must be unpolarized, whereas for the rotating analyzer the detector must be polarization insensitive. Because the latter can be achieved more readily, the rotating analyzer ellipsometer is more accurate. Comparisons of measurements by rotating analyzer and manual four-zone null techniques show that the former can achieve an accuracy better than 0.1° relative to the latter.

In the rotating compensator ellipsometer, the fixed polarizer is mounted before the sample, and the rotating compensator and fixed analyzer are mounted after the sample. Several advantages of this design over the simpler rotating analyzer design justify the added complexity of the required $\lambda$-dependent calibration for $\rho_C$. These include the ability to (i) determine the sign of $\Delta$, (ii) obtain accurate $\Delta$ values for nearly linear polarization states, and (iii) deduce the degree of polarization $p$ of the light beam reflected from the sample. This latter parameter assists in characterizing nonideal samples having macroscopic nonuniformities such as roughness or thickness gradients that generate a distribution of polarization states in the beam reaching the detector. For the rotating compensator system, the detector irradiance obeys Equation (53):

$$I(t) = I_0[1 + \alpha_2 \cos(2wt + \varphi) + \beta_2 \sin(2wt + \varphi)] + \alpha_4 \cos(4wt + \varphi) + \beta_4 \sin(4wt + \varphi)]$$

where $wt + \varphi$ represents the time dependence of the compensator angle, $\varphi$ is the phase angle, and $[(\alpha_m, \beta_m); m = 2, 4]$ are normalized $2\omega$ and $4\omega$ Fourier coefficients. These coefficients are deduced by Fourier analysis of the detector signal. From the Fourier coefficients, the three parameters $(Q, \chi, p)$ that characterize the normalized Stokes vector of the light beam just after reflection from the sample can be obtained by solving Equations (54–57): (37)

$$\alpha_2 = \frac{p \sin \delta_c \sin 2\chi \sin 2A}{1 + \{p \cos^2(\delta_c/2) \cos 2\chi \cos 2(A - Q)\}}$$

$$\beta_2 = \frac{-p \sin \delta_c \sin 2\chi \cos 2A}{1 + \{p \cos^2(\delta_c/2) \cos 2\chi \cos 2(A - Q)\}}$$

$$\alpha_4 = \frac{p \sin(\delta_c/2) \cos 2\chi \cos 2(A + Q)}{1 + \{p \cos^2(\delta_c/2) \cos 2\chi \cos 2(A - Q)\}}$$

$$\beta_4 = \frac{p \sin(\delta_c/2) \cos 2\chi \sin 2(A + Q)}{1 + \{p \cos^2(\delta_c/2) \cos 2\chi \cos 2(A - Q)\}}$$

For samples in which $p = 1$, i.e. no polarization occurs, $(\psi, \Delta)$ can be deduced from $(Q, \chi)$ using Equations (58–60):

$$\cos 2\psi = \frac{\cos 2P - \cos 2Q \cos 2\chi}{1 - \cos 2Q \cos 2\chi \cos 2P}$$

$$\sin \Delta = \frac{\sin 2\chi(\cos 2\psi \cos 2P - 1)}{\sin 2\psi \sin 2P}$$

$$\cos \Delta = \frac{\cos 2\chi \sin 2Q (1 - \cos 2\psi \cos 2P)}{\sin 2\psi \sin 2P}$$

The importance of the rotating compensator system is its ability to maintain high precision, independent of $(\psi, \Delta)$, a feature also common to the null ellipsometer. Its accuracy is also much improved over the rotating polarizer and analyzer systems when the reflected beam is nearly linearly polarized. In addition, the rotating-compensator system is not affected by errors caused by source polarization or detection system polarization sensitivity since both the polarizer and analyzer are fixed. The main difficulty of the rotating-compensator ellipsometer is in the development of a first-order compensator for error-free spectroscopic operation. Compensators constructed from quartz or MgF$_2$ biplates or mica sheets can exhibit oscillatory spectral artifacts due to plate misalignment and multiple reflections between parallel surfaces of the device. (38)

4.1.4 Phase Modulation Ellipsometers

For phase modulation ellipsometers, the fixed compensator in the generic ellipsometer design of Figure 4 is replaced by a birefringent phase modulator, e.g. a Pockels cell or silica piezobirefringent element (see Figure 7). This provides a sinusoidal relative retardation $\delta$ between orthogonal field components given by

$$\delta(t) = \delta_m \sin \frac{w_m t}{\pi}$$

where $w_m/2\pi$ is typically 50 kHz and $\delta_m$ is proportional to $V_m/\lambda$, where $V_m$ is the modulator drive voltage. In practice, $A$ and the polarizer angle relative to the phase modulator angle, $P - M$, are both set to $45^\circ$. Assuming no depolarization, this leads to the detector irradiance given by Equation (61):

$$I(t) = I_0[1 + \sin 2\psi \sin \Delta \sin[\delta(t)] + (\sin 2M \cos 2\psi + \cos 2M \sin 2\psi \cos \Delta) \cos[\delta(t)]]$$
Alternatively in configuration III, one can apply Equations (62) and (63). Because only \( \sin \Delta \) is measured in configuration III, both \( -180^\circ < \Delta \leq 180^\circ \) and \( \pm 180^\circ - \Delta \) are solutions to Equation (65). In configuration III with \( \Delta \) near \( 90^\circ \), such as may occur for bulk metal surfaces, the precision and accuracy in \( \Delta \) is poor. Measurements in both configurations solve these problems and, in addition, when depolarization occurs yield \( p \):

\[
p = (N_{III}^2 + C_{II}^2 + S_{III}^2)^{1/2}
\]

The quantities in Equation (66) can also be obtained using a polarization state detector design that incorporates a Wollaston prism in place of the analyzer. In this design, the reflected beam is decomposed into orthogonal linearly polarized beams that are measured by two PMTs.

The precision of the phase modulation and rotating analyzer ellipsometers are comparable when measured under optimum conditions for both instruments.\(^{(49)}\) The advantage of the former is its high speed when operated using the Fourier analysis scheme. A high speed is useful in a number of real time studies of reactions at interfaces, film growth at high rates, and ion, laser, and thermal processing of materials. Unfortunately, the precision of the instrument degrades rapidly under these measurement conditions and the monolayer sensitivity is lost. An advantage of the phase modulation ellipsometer over the rotating polarizer or analyzer systems is its immunity to source polarization and detector polarization sensitivity. The disadvantage of the phase modulation ellipsometer is its greater complexity. Nonideal behavior of the modulator, e.g. effects of multiple harmonics and static birefringence, imply that greater care is required to achieve high accuracy operation in comparison to the rotating polarizer and analyzer systems.

### 4.2 Spectral Range

The spectral range of an ellipsometer determines the physical and chemical information accessible from the measured dielectric function.\(^{(62)}\) The most common ellipsometers operate from the ultraviolet to the near-infrared and provide information on the electronic transitions between states in the valence and conduction bands located within \( \Delta E \sim \pm 5 \text{ eV} \) of the Fermi level.\(^{(5)}\) The optical absorption and dispersion associated with these transitions allow the material density, phase (e.g. crystalline versus amorphous), composition, and temperature to be established, assuming that suitable databases exist. Ellipsometers operating over a wide spectral range of the infrared (700–7000 cm\(^{-1}\)) have increased in popularity recently.\(^{(6,42)}\) The dielectric functions of materials in the infrared provide information on vibrational excitations that allow the chemical bonds to be identified at the surface or within the bulk of the materials. In addition, the dielectric functions in the infrared allow

---

Dalby, Rev. Sci. Instrum., 53, 969–977 (1982).\(^{(40)}\))
free electron transitions to be characterized in conducting materials such as metals and doped semiconductors. Finally, specialized instruments utilizing synchrotron radiation sources have also been developed to span spectral ranges outside the ultraviolet to mid-infrared. With such instruments, materials have been measured in the far-infrared (20–800 cm\(^{-1}\)),\(^{43,44}\) the vacuum ultraviolet (50–200 nm),\(^{45}\) and the extreme ultraviolet (∼10 nm).\(^{46}\) In the far infrared, the dielectric functions of solids reveal excitations of vibrational modes, excitations across the energy gaps of superconductors, as well as collective excitations of charge and spin density waves. In the vacuum and extreme ultraviolet, the dielectric functions provide information on core electron transitions. For the different spectral ranges, the ellipsometer components, including the source, the polarizers, the compensator, and the spectrometer, must be chosen for optimum performance.

In the most common ultraviolet to near-infrared ellipsometer, a broad-band Xe arc lamp is used as the source.\(^{33}\) This can provide useful output from 200–300 to 1000 nm. High quality polarizers for this range are constructed from calcite prisms with a usable lower wavelength limit of ∼220 nm. Quartz or magnesium fluoride polarizers can extend the response to less than 200 nm. The problem with quartz polarizers is their optical activity. As a result, the polarization state after transmission through the polarizer is not linear, but exhibits a slight ellipticity which must be corrected in data reduction to achieve an accuracy better than 0.1°.\(^{33,34}\) Birefringent compensators used in transmission over the ultraviolet to near-infrared range consist of pairs of fixed or adjustable (Babinet–Soleil) quartz or MgF\(_2\) plates; a mica sheet can also be used, but with a restricted spectral range (300–800 nm). For such birefringent compensators, the phase shift \(\delta_c\) is approximately inversely proportional to \(\lambda\). Three-reflection compensators are also available made from vitreous silica with the advantage of having a nearly \(\lambda\)-independent \(\delta_c\).\(^{47}\) Phase modulators for the ultraviolet to near-infrared range are also usually constructed from a vitreous silica element that is subjected to a periodic stress.\(^{39–41}\) This device can cover the spectral range from 200 to 1000 nm providing that the drive voltage is adjusted to cancel the \(\lambda\)-dependence of the phase shift. The monochromators or spectrometers used in the ultraviolet to near-infrared employ either rotatable prisms, gratings, or combinations of the two in order to disperse the incident light. The most popular detector for this spectral range is the PMT, which is typically sensitive from 200 to 800 nm. Silicon photodiodes can extend the spectral range to 1000 nm in the near-infrared. For photometric ellipsometers, one must ensure that the detector remains within its linear range of operation throughout the wavelength scan.\(^{33}\)

Ellipsometers operating in the mid-infrared range have been designed based on the rotating-element and phase-modulation principles.\(^{42}\) For both instruments, the radiation source is a SiC globar and Michelson interferometer for wavelength scanning based on Fourier transform principles, and the detector employs a cooled mercury cadmium telluride (Hg\(_{1−x}\)Cd\(_x\)Te) element for highest sensitivity. Figure 8 shows a typical schematic of a rotating-element infrared spectroscopic ellipsometer.\(^{48}\) Because the frequency of wavelength scanning for the instrument in Figure 8 (∼100 Hz) is comparable with the rotation frequency of the rotating elements (e.g., the polarizer and compensator), then the waveform \(I(t)\) at the detector must be reconstructed from wavelength scans performed at selected settings \(P\) and \(C\). This approach is in contrast to the rotating element instrument operating from the ultraviolet to near-infrared in which the optical elements are rotated continuously at a number of settings \(\lambda\). In phase-modulation infrared SE (IRSE), however, the frequency of wavelength scanning is much lower than the phase modulation frequency.\(^{42}\) As a result, both the interferometer and the modulator can be operated simultaneously, and the waveform of Equation (61) can be extracted using double modulation principles. Phase-modulation IRSE is claimed to be faster and thus more efficient than the rotating-element method.\(^{48}\)
suitable for real time characterization of film surfaces. Sensitivities at the partial monolayer level can be obtained in both cases with long averaging times. For example, fluctuations in $\Delta$ of $\delta \Delta \sim \pm 0.01^\circ$ have been measured in phase-modulation IRSE with a 15 min integration time.

The optical elements used in IRSE must be fabricated from materials with high infrared transmission. The most common polarizer consists of a ZnSe plate coated with a wire grid. The problem with such a polarizer is its poor attenuation ratio, i.e. the ratio of the irradiances transmitted by identical polarizers in parallel and crossed orientations, which ranges from $\sim 0.002$ at 700 cm$^{-1}$ to $\sim 0.05$ at 6000 cm$^{-1}$. For comparison, the attenuation ratios of MgF$_2$ and calcite polarizers operating in the ultraviolet to near-infrared are $10^{-4}$ to $10^{-6}$. Polarizers based on Brewster angle reflections at the surfaces of a pair of Ge crystals provide a much improved attenuation ratio of less than $2 \times 10^{-4}$; however, such polarizers are difficult to align. A reasonable trade-off in rotating-element IRSE is to employ a fixed Brewster angle polarizer at the output of the interferometer and a rotatable wire grid analyzer in front of the detector. This configuration simplifies correction for the attenuation ratio of the analyzer, which is necessary in order to obtain an accuracy better than $\pm 1^\circ$. A compensator is desirable in the rotating analyzer IRSE since many samples of interest exhibit $\Delta$ near $0^\circ$ or $\pm 180^\circ$ over a wide spectral range. Compensators in the transmission geometry are generally not used in infrared ellipsometers because of their limited spectral range. Instead, compensators are employed based on the principles of external reflection from a thin film or total internal reflection within a prism. For example, a ZnSe prism in which the beam reflects from an internal surface can serve as a compensator. Finally, the piezobirefringent modulator used in phase-modulation IRSE is constructed from ZnSe as well and is operated at a frequency of 37 kHz.

### 4.3 Spatial Resolution

Conventional ellipsometers operating from the ultraviolet to near-infrared probe the sample with a typical 1–5 mm diameter beam at $\phi_i = 50 – 75^\circ$. All physical parameters of the sample including the layer thicknesses and dielectric functions must be uniform over the probed area, unless provisions for nonuniformity are included in data analysis. In many situations, information is sought on macroscopically nonuniform surfaces, specifically, surfaces whose properties differ on scales ranging from greater than the probe wavelength (>5 µm) to less than the beam size (<5 mm). For example, in studies of the oxidation of polycrystalline materials, the oxide growth kinetics, and hence the layer thicknesses, are different on differently oriented grains. In addition, in studies of corrosion, passive layer breakdown on a metal surface may occur locally, signaling the onset of pitting. Finally, in studies of the processing of semiconductor structures used in microelectronics, the surfaces are patterned with different multilayer stacks on different areas of the surface.

If the nonuniformity over the surface of a particular sample is sufficiently well known, then conventional ellipsometry can be performed and the nonuniformity can be extracted in the data analysis. For an incident beam with lateral spatial coherence greater than the scale of the nonuniformity, the amplitude reflection coefficient for the interfaces can be calculated as the surface area-weighted average of the individual reflection coefficients for the regions of the sample with different properties. Such an approach has been applied to characterize nucleating films consisting of large well-separated crystallites. For an incident beam with lateral coherence less than the scale of the nonuniformity, the irradiance at the detector can be calculated as a surface area-weighted average of individual irradiances. This method has been used to characterize film thickness distributions extending over the beam area. Macroscopically nonuniform surfaces often lead to pseudodepolarization of the reflected beam, meaning that the reflected beam is characterized by an incoherent superposition of polarization states each associated with an area element of the surface having a unique structure and optical properties. Thus, in measurements in which a single beam probes a nonuniform surface, it is also important to measure $p$ and include this parameter in the data analysis.

In spite of the recent advances in data analysis for characterization of macroscopically nonuniform samples, such samples are best studied with an ellipsometer specifically designed for this purpose. Two different approaches for performing spatially resolved ellipsometry have been developed and a resolution of about 10 µm has been achieved in both cases.

The first instrument uses focusing systems mounted before the polarizer and after the analyzer in the rotating analyzer configuration to obtain a spot size of 10 µm at the sample for ME. An ellipsometric image of a surface can be generated serially by sample translation. The advantage of this approach is that, for selected points on the surface, spectra from the ultraviolet to near-infrared can be collected, which are usually necessary for the analysis of complex sample structures. Such a capability makes this instrument design best suited for semiconductor wafer mapping. A disadvantage is the inordinate time required for serial mapping combined with serial collection of spectra using a single PMT. Recently, a similar instrument has been developed in the rotating polarizer configuration, incorporating a photodiode array that...
allows spectra to be collected in parallel, thus reducing the mapping time by two orders of magnitude.\(^{(53)}\)

The second instrument for spatial resolution uses the generic ellipsometer configuration of Figure 4 but with a source consisting of a laser, coherence scrambler, and collimator.\(^{(54)}\) A lens after the sample images the illuminated surface through the analyzer onto a two-dimensional CCD for parallel detection. Images collected at three polarizer or analyzer angles permit construction of a 480-line × 512-pixel (\(\psi, \Delta\)) image in 40 s. The advantage of the CCD-based instrument for IE lies in the dynamic imaging capability that can be achieved through improvements in speed made possible by advances in CCD technology and image processing hardware and software. The disadvantage is the single wavelength operation which makes the instrument less suitable for the interpretation of complex sample structures.

The speed of IE for the analysis of simple sample structures (e.g., a single nonabsorbing film of known \(n_l\) on a substrate of known \(N_s\)) can be improved by using the configuration of Figure 4 in the off-null mode.\(^{(55)}\) In this mode, the angles \(P\) and \(A\) are set to obtain a null image for the bare substrate. During nonuniform film growth on the substrate, the irradiance that develops at a given pixel is proportional to the square of the film thickness at the conjugate point on the sample. As a result, the image in the irradiance provides a thickness map over the surface. The off-null imaging ellipsometer has been applied as a “proof-of-concept” affinity biosensor.\(^{(55)}\) An example of IE results from such an instrument is given in Figure 9. The sample in this case is a 15 × 25-mm hydrophobic silicon wafer onto which three different proteins have been adsorbed in pairs of 4-mm spots. The three proteins are fibrinogen (Fib), human serum albumin (HSA) and human immunoglobin G (h-IgG). The thickness of the HSA film is 2 nm. (Reproduced from H. Arwin, Thin Solid Films, \textbf{313–314}, 764–774, Copyright (1998) with permission of Elsevier Science.\(^{(57)}\))

Of sample features can be discussed in relation to measurements performed on a conventional ellipsometer: (i) the atomic scale (\(\sim 0.1–1\) nm); (ii) much greater than the atomic scale, but less than the wavelength of the probe light (\(\sim 10–100\) nm); (iii) the probe wavelength scale (\(\sim 200\) nm–1 \(\mu\)m), (iv) much larger than the probe wavelength, but less than the beam size (\(\sim 5\) \(\mu\)m–1 mm); and (v) larger than the beam size (>1 mm). Whether these features can be studied by ellipsometry and, if so, how the information can be extracted is one issue addressed in this section. The second issue concerns the deviations from ideality in the nature of real surfaces and interfaces. Obviously the concept of a mathematically abrupt interface as employed in section 3 is an idealization; however, surfaces can be prepared to conform as closely as possible to this idealization. Alternatively, nonidealities can be taken into account in data analysis.

First the effect of atomic structure, microstructure, inhomogeneity, and nonuniformity of the sample on the ellipsometry measurements will be discussed. From section 4.3, it should be clear that if the sample is nonuniform on a scale larger than the beam size, then the conventional analysis is valid, and the sample can be mapped by translating it in the plane of the surface. If the sample is nonuniform on a scale smaller than the beam size, but larger than \(\lambda\) and the lateral spatial coherence of

\begin{figure}

\end{figure}
ELLIPSOMETRY IN ANALYSIS OF SURFACES AND THIN FILMS

the beam, then the nonuniformity can be detected through its effect on \( p \). In this case, averaging methods using incoherent summation of irradiances may be effective in characterizing the nonuniformity, providing that its origin is sufficiently well known.\(^{2(4)}\) A better approach to characterize such nonuniformity is with IE or ME (see section 4.3).

Inhomogeneity on the scale of \( \lambda \) is perhaps the most difficult to characterize. If the inhomogeneity is extensive, then there may be no significant irradiance in the specularly reflected beam and the measurement may fail. At the other extreme, if the inhomogeneity is caused by a low density of defects in the sample or on its surface, then the defect-free regions will generate a well-defined specular beam while the defects will scatter light. An ellipsometry measurement is relatively insensitive to such defects, whereas a reflectance measurement is much more strongly affected since the scattering generates a loss. As defects increase in density on the surface, it is useful to determine the beam parameter \( p \) along with the sample parameters \((\Psi, \Delta)\), e.g. with a rotating compensator or dual-channel phase modulation ellipsometer, to assess the possible effect of overlapping scattered and specular light at the detector.\(^{(56)}\) In such cases, analysis of the \((\Psi, \Delta)\) data can provide the specular sample properties, which can be applied to predict the reflectance \( R \) that would be observed if the sample was free of inhomogeneities. An analysis of the deviation between the measured and predicted reflectance can provide information on the nature of the inhomogeneity.\(^{(57)}\) Thus, an ellipsometer that can simultaneously provide the sample parameters \([\Psi, \Delta, R]\) and the reflected beam parameter \( p \) is beneficial.

Sample microstructure much larger than the atomic scale, but smaller than \( \lambda \) can be characterized with ellipsometry by applying effective medium theories.\(^{(58)}\) Such theories allow the optical properties of a composite to be calculated from the optical properties of the component materials and their volume fractions. The simplest effective medium theories have the form:

\[
\frac{\varepsilon - \varepsilon_h}{\varepsilon + \kappa \varepsilon_h} = f_a \frac{\varepsilon_a - \varepsilon_h}{\varepsilon_a + \kappa \varepsilon_h} + f_b \frac{\varepsilon_b - \varepsilon_h}{\varepsilon_b + \kappa \varepsilon_h} + \cdots
\]

(67)

where \( \varepsilon \) is the dielectric function of the composite, which is a mixture of two or more components having volume fractions \( f_a, f_b, \ldots \) and dielectric functions \( \varepsilon_a, \varepsilon_b, \ldots \). In Equation (67), \( \varepsilon_h \) is the host medium dielectric function, and \( \kappa \) is a parameter that describes the screening at the phase boundaries. Effective medium theories used for solid state applications include the Bruggeman theory in which case \( \varepsilon_b = \varepsilon \) and \( \kappa = 2 \), and the Maxwell–Garnett theory in which case \( \varepsilon_b \) is the dielectric function of the dominant component and \( \kappa = 2 \). The choice \( \kappa = 2 \) in both cases corresponds to spherical inclusions, i.e. isotropic microstructure in three dimensions.

The Bruggeman theory has been applied most widely to model the optical properties of thin films containing regions devoid of atoms (i.e. voids) or films consisting of multiple phases (e.g. an amorphous solid with crystalline inclusions).\(^{(58)}\) In these cases, an analysis provides the void or crystalline volume fraction. The Bruggeman theory has also been applied to model surface or interface roughness as one or more layers consisting of a mixture of the underlying and overlying materials such that the volume fraction(s) and layer thickness(es) are to be determined. Finally, effective medium theories have been used to model nucleating thin films as a mixture of bulk material and voids, representing the clusters and the free space between clusters, respectively. The Bruggeman theory has been applied for nucleating semiconductor films, whereas a form of the Maxwell–Garnett theory has been applied for nucleating metal films. Using such a model, the thickness and void volume fraction of the nucleating film is determined. Further discussion of the data analysis procedures will appear in section 4.5.

Effective medium theories begin to lose their validity when the scale of the microstructure approaches within an order of magnitude of \( \lambda \).\(^{(59)}\) In this regime, light scattering comes into play as described earlier, and the assumptions on which the theories are based break down. In the opposite limit, if the microstructure becomes small enough so that the individual inclusions no longer exhibit the bulk dielectric functions, then size-modified versions must be used instead in Equation (67). This lower limit depends on the material. For example, crystalline silicon exhibits size-dependent optical effects for grain sizes as large as 100 nm, whereas in amorphous silicon, size-dependent effects have not been identified even for the smallest clusters.\(^{(60)}\) Thus, in the latter case, the optical properties of amorphous silicon containing a distribution of atomic scale voids can be predicted from the optical properties of dense amorphous silicon. In contrast, for a crystalline material, atomic scale heterogeneities alter the basic electronic structure and require that the optical properties of the materials be characterized individually as a function of their composition. The same strategy is needed in the case of crystalline and amorphous alloys, an example being Si\(_{1-x}\)Ge\(_x\). In general, size effects render the analysis extremely difficult in all but the simplest situations.

This section will conclude with a discussion of deviations exhibited by real samples from mathematically exact behavior in the case of single interfaces. This problem has a long history starting with Paul Drude and Lord Rayleigh. Drude noticed the gradual change over time in the polarization state of light reflected from a freshly cleaved Sb\(_2\)S\(_3\) crystal and attributed it to contamination
arising from the reaction of the top layers of the crystal with the ambient medium.\(^9\) Rayleigh noticed that the light reflected from a water surface at the Brewster angle showed residual ellipticity and attributed the effect to a thin “greasy contamination” layer.\(^{61}\) He concluded that “it is even possible that there would be no sensible ellipticity for the surface of a chemically pure body”. Thus, the basic problem of sample preparation and cleanliness in polarization state measurements was recognized more than a century ago. Today researchers struggle with the same issues and recognize not only contamination, but also surface roughness, and even surface reconstruction as effects that distort the experimental data from results predicted on the basis of models assuming mathematically abrupt interfaces.

One might expect that the best way to prepare a bulk material for SE measurement of its dielectric function is to exploit the methods of surface science.\(^62\) This would entail mounting an UHV system at the ellipsometer axis and measuring the sample in situ through UHV windows before and after desorption of native oxides through annealing or sputter etching. Such treatments can generate microscopic roughness or damaged surface regions, however, whose effects on the SE data are often larger than that of the native oxide. Thus, a superior approach is to prepare the material in situ and measure it under UHV prior to exposure to air. In this case, one need only worry about the roughness on the as-prepared surface and any surface reconstruction that occurs. In fact, measuring the material during preparation as described in section 5 often allows surface layers that have different optical properties from the underlying bulk to be deduced, and then taken into account in the analysis. Unfortunately, the technical complexity has limited the application of this approach. In the absence of UHV capabilities, in situ chemical cleaning and chemomechanical polishing have been used most widely to prepare sample surfaces.\(^63\) In such experiments, an open-windowed cell is fixed at the ellipsometer axis which allows the sample to be mounted and its surface to be exposed to various treatments while being measured in situ. In fact, a “biggest is best” criterion in \(\langle \varepsilon_2 \rangle\) has been developed to monitor the success of the treatments. With this criterion, the treatments leading to the largest value of \(\langle \varepsilon_2 \rangle\) at a particular wavelength provide the surface that is the closest to a mathematically abrupt termination of the bulk structure and, thus, the closest representation of \(\varepsilon_2\) for the bulk material. When these conditions are reached, then the surface can be measured by SE under a \(\text{N}_2\) flow to maintain the clean surface. The resulting spectrum in \(\langle \varepsilon \rangle\) deduced from \((\psi, \Delta)\) is as close as possible to the true dielectric function \(\varepsilon\).

Figure 10 provides an example of this approach for crystalline Si.\(^{64,65}\) In this case different crystal faces are exposed to chemical and chemomechanical treatments in an attempt to obtain the highest value of \(\langle \varepsilon_2 \rangle\) at \(\lambda = 291.8\) nm, where the “biggest is best” criterion holds. Because Si is cubic, mathematically abrupt terminations of the bulk should provide the same data for \(\varepsilon_2\) for all crystal faces. Figure 10 shows that it is easiest to obtain an abrupt \((111)\) surface, whereas it is most difficult to obtain an abrupt \((100)\) surface. The trajectory labeled “damage” indicates the expected trend in the \((\langle \varepsilon_1 \rangle, \langle \varepsilon_2 \rangle)\) data if roughness developed on the treated \((111)\) surface. A comparison of this trend with the data for different crystal faces shows that roughness can account for much of the differences between the best surfaces. The trajectory labeled “overlay” is the expected trend if an \(\text{SiO}_2\) layer developed on the treated \((111)\) surface. A comparison of this trend with the data for individual crystal faces shows that much of the improvement in the surfaces upon cleaning can be attributed to oxide removal. The arrow at the top right indicates the most recent results for the \((111)\) Si surface. The points at the top show that much better data for the \((100)\) surface and comparable data for the
(111) surface can be obtained from epitaxially grown Si measured immediately upon removal from the deposition chamber.

Techniques such as those shown in Figure 10 have led to the development of an extensive database for the optical properties of various materials and this database continues to be improved.\(^{(13,66,67)}\) With an accurate database, information can be obtained on the nonidealities in more complex single layer and multilayer structures. For example, using the database one can predict the multiple \((\psi, \Delta)\) data sets to be expected for a thin film of arbitrary thickness \(d_j\) which presents ideal interfaces to the ambient medium and to the underlying substrate. Inevitably, an exact fit to the data for a real film cannot be obtained for any one choice of film thickness. Additional layers can then be introduced into the model in an attempt to understand the origin of the deviations in the data. For example, native oxides or roughness layers can be added to model a nonideal film surface, and interface roughness or chemical interaction regions can be added to model a nonideal film/substrate interface. In situ surface cleaning techniques similar to those mentioned above can also be applied in an attempt to reduce the effects of a nonideal ambient/film interface. In the next section, the discussion will focus on the analysis methods for multiple \((\psi, \Delta)\) data sets collected on complex structures such as these.

### 4.5 Data Analysis

The analysis of multiple \((\psi, \Delta)\) values has been described briefly in sections 3.3 and 3.4 for single and multilayer samples. Next, general data analysis procedures will be described in greater detail. Owing to the widespread use of SE, it is assumed that the minimum data set consists of continuous spectra of 50–300 \((\psi, \Delta)\) values.\(^{(5)}\) Multiple spectra can also be collected for different angles of incidence, in a method called variable angle SE.\(^{(26)}\) For different incident polarization states, in a method called generalized ellipsometry.\(^{(25)}\) The availability of multiple spectra further enhances the analytical capabilities of SE. We assume that SE is performed ex situ, so that only the final sample state is accessible. Analysis techniques specific to RTSE data will be described in section 5.2. Here, two categories of the data analysis method will be described. In the first category, the analysis of sample optical properties and structure is reduced to the determination of several \(\lambda\)-independent quantities. Then least squares regression analysis can be applied to find the parameter values that minimize the deviations between the experimental data and the simulated results. In the second category, the dielectric function of one component of the sample is determined by exact numerical inversion of the experimental data. In addition, by constraining the form of this dielectric function, as many as three \(\lambda\)-independent structural parameters, usually thicknesses, can be deduced.

In the first general data analysis procedure, a model for the sample is proposed at the outset.\(^{(69)}\) The model includes the number of layers \(m\) and the expected nature of these layers. The unknown \(\lambda\)-independent free parameters in the analysis will include the layer thicknesses, \(d_j; j = 1, \ldots, m\). The optical properties of the layers can be incorporated into the model by applying one or more of at least four different strategies.\(^{(28)}\)

1. Dielectric functions from previously determined databases can be used. In this case, no additional free parameters are introduced.
2. An effective medium theory can be used for any layers that are composite materials. In this case, the additional \(\lambda\)-independent parameters are the component volume fractions. The dielectric functions of the component materials can be obtained using any of the other three strategies.
3. A parameterization formula for one or more of the dielectric functions can be used. In this case, the \(\lambda\)-independent parameters are defined by the formula.
4. The \(\lambda\)-independent parameters from the strategy 3 can be expressed as functions of the composition of the material, thus allowing the composition to be used directly as a free parameter.

Once the model and the variable parameters are identified, often with a simulation program, initial guesses for the parameters are made by performing a grid search within the simulation program. Then a least squares regression analysis routine provides the successive parameter adjustments required to minimize the error function, which can be computed as the biased estimator of the mean square deviation between the data and calculated fit.\(^{(28)}\) Once the best fit is obtained for a given model, complexities are added or other models are tested in an attempt to identify the correct model. Such identification is made on the basis of (i) the reasonableness of the model and best fit parameters, (ii) the biased estimator, i.e. the magnitude of the error function relative to the accumulated experimental errors in the data, and (iii) the statistical information deduced from the best fit, including the confidence limits on the parameters and the elements of the parameter correlation matrix. The power of this technique has been extolled while potential pitfalls resulting from its abuse have been outlined.\(^{(28)}\)

As an example of this data analysis approach, it is helpful to consider the case of a known substrate coated with an absorbing film of unknown optical properties,
such that the dielectric function of the film must be parameterized. One of the simplest ways of doing this is to assume a sum of $m_\infty$ damped harmonic oscillators (often referred to as Lorentz oscillators) (Equation 68):\

$$\varepsilon(E) = \varepsilon_\infty + \sum_{j=1}^{m_\infty} \frac{A_j^2}{E_j^2 - E^2 + i\Gamma_j E}$$

(68)

Here $E = hc/\lambda$ is the photon energy, $\varepsilon_\infty$ is a constant contribution to the real part of the dielectric function, and $\{A_j, E_j, \Gamma_j\}$ denote the amplitude, resonance energy, and broadening parameter for the $j$th oscillator. Thus, if analysis assuming a single oscillator is attempted, then least squares regression involves fitting to determine five free parameters, $d_i, \varepsilon_\infty$, and $\{A_j, E_j, \Gamma_j\}$. For each additional oscillator incorporated into the dielectric function, an additional three parameters must be determined. If a roughness layer is known to exist on the film, then one additional parameter needs to be determined, the roughness layer thickness (assuming a void volume fraction of $0.5$). For example, the dielectric functions of bulk $Al_{1-x}Ga_x$As crystals have been modeled using Equation (68) with 7 oscillators and 22 free parameters, $\varepsilon_\infty$ and $\{A_j, E_j, \Gamma_j\}; j = 1, \ldots, 7$, each of which could be expressable as simple quadratic functions of the alloy composition $x$.\textsuperscript{(70)} As a result, a database of 66 parameters is sufficient to parameterize the dielectric function of the alloys fully and thus calculate $\varepsilon(E)$ for any $x$. With this database, analysis of SE measurements of a heteroepitaxial film of $Al_{1-x}Ga_x$As on GaAs can provide $d_i$ and $x$. This demonstrates the importance of dielectric function parameterization and the development of databases. More sophisticated methods than that of Equation (68) have been developed for dielectric function parameterization based on an analysis of the energy band structures of the materials.\textsuperscript{(71)}

In the second general data analysis procedure, a single unknown dielectric function is extracted from the ($\psi$, $\Delta$) spectra, without making any assumptions about its functional form. In addition, one or more $\lambda$-independent structural parameters can be determined.\textsuperscript{(72)} At first sight, this procedure may seem impossible since more parameter values are deduced than data available. The additional structural parameters can be determined, however, based on the constraint that the dielectric function $\varepsilon = \varepsilon_1 - i\varepsilon_2$ extracted from ($\psi$, $\Delta$) by exact numerical inversion must show physically reasonable characteristics. One may stipulate that $\varepsilon_2$ vanish over some region of the spectrum if the material is a semiconductor or dielectric, or that $\varepsilon$ show no artifacts due to features from the dielectric function of the substrate or from the interference pattern in the ($\psi$, $\Delta$) data. Thus, this procedure is performed by (i) guessing the unknown $\lambda$-independent parameters, (ii) applying a nonlinear numerical analysis method (such as that of Newton) to determine the remaining two unknowns ($\varepsilon_1$, $\varepsilon_2$) from ($\psi$, $\Delta$), (iii) inspecting ($\varepsilon_1$, $\varepsilon_2$) for the desired characteristics, and (iv) adjusting the initial guesses successively in order to obtain these characteristics. A specific application of this analysis procedure is provided in the next section.

### 4.6 Applications of the Characterization of Materials, Thin Films, and Structures

In this section, selected applications will be described in which SE has been employed to determine the dielectric function of bulk materials and the dielectric function and microstructure of thin films. In the first part of this section, a novel method is described for determining the infrared optical properties of liquids using an infrared spectroscopic ellipsometer combined with an attenuated total reflection cell. In the second part, the application of different approaches for the complete analysis of SE data on thin and thick films will be provided. The first two examples in the second part will focus on the analysis of relatively thin (<50 nm) polymeric and protein films, while the second two examples will focus on thick (>500 nm) inorganic films.

#### 4.6.1 Bulk Surfaces: Optical Property Measurement

The analysis of SE data to obtain the dielectric function $\varepsilon_s$ of a bulk material is straightforward; one simply substitutes the angle of incidence $\phi_i$, the ambient medium dielectric function $\varepsilon_a$, and the measured ($\psi$, $\Delta$) spectra into Equation (23). As discussed in section 4.4, however, the major difficulty rests in the uncertainty about the nature of the interface.

Here, an application of IRSE is described, namely the measurement of the optical properties of liquids using an attenuated total reflection cell.\textsuperscript{(48)} The instrument is shown in Figure 8, and the measurement configuration is shown in Figure 11(a). The ambient medium is a ZnSe 45° prism that encloses the liquid within a reservoir. The infrared beam enters the first prism face at normal incidence, strikes the ZnSe/liquid interface at $\phi_i = 45^\circ$, and exits through the second prism face. Total internal reflection occurs for a liquid index of refraction $n_s < 1.7$; however, IRSE does not rely on this condition. The major errors in this measurement arise from sample nonidealities. For example, the ZnSe/liquid interface is most likely to be far from ideal even if the liquid itself is contaminant free. Surface roughness, a native oxide, and contamination are likely to be found on the ZnSe side of the interface. The advantage of the inverted configuration in Figure 11(a) is that a measurement performed in the absence of a liquid can be used to obtain information on the perfection of the interface. In such analyses, the optical properties of the ZnSe ambient medium from a
pre-existing database are employed. Figure 11(b) shows typical results obtained for Krytox 16256N, a liquid lubricant made by DuPont, described in terms of $(n_s, k_s)$. Once the optical properties of the bulk lubricant are available, the results can be added to a database that will allow the thickness and surface coverage of a thin lubricant layer to be determined. For example, partial surface coverage by a lubricant can be modeled as a layer consisting of a mixture of bulk lubricant and void using the Bruggeman theory (see section 4.4).

4.6.2 Thin Films: Thickness and Optical Property Measurement

The analysis of SE data for thin film structures is more difficult than for bulk materials. General data analysis approaches for single and multilayer structures have been described in section 4.5. Here the approaches are demonstrated for the characterization of a thin polypyrrole film and a much thinner film of lactoperoxidase (LPO), both on gold substrates.

Electrically conducting polypyrrole films for SE studies were prepared by electrodeposition on opaque Au substrates in an electrochemical cell using an aqueous solution of the monomer with a KNO₃-based electrolyte. The $(\psi, \Delta)$ spectra were measured in situ to avoid reaction of the film with ambient air. SE was performed using a rotating polarizer multichannel ellipsometer with an acquisition time of 3.2 s (see section 5.1). The $(\psi, \Delta)$ spectra were analyzed using a single layer model to determine the dielectric function $\varepsilon_f$ and thickness $d_f$ of the polypyrrole film. The well-defined features in the dielectric function $\varepsilon_s$ of the Au substrate near 2.5 eV facilitated such an analysis. Thus, $d_f$ was chosen by trial and error to eliminate the Au-related
Figure 12 Second derivatives of the real parts of trial dielectric functions for a polypyrrole (PPy) thin film calculated assuming a single-layer optical model consisting of H2O/PPy/Au using different PPy thicknesses. Corresponding results for the Au substrate are also shown. The correct thickness of the PPy film, 49 nm, minimizes the artifact in the derivative spectrum arising from the dielectric function of the substrate. (Reproduced from Y.-T. Kim, D.L. Allara, R.W. Collins, K. Vedam, Thin Solid Films, 193–194, 350–360. Copyright (1990) with permission of Elsevier Science.73)

artifacts at 2.5 eV in $\varepsilon_f$, which was obtained by exact numerical inversion of the $(\Psi, \Delta)$ spectra, as described in section 4.5. Figure 12 shows derivative spectra plotted versus energy for several trial $\varepsilon_{1f}$ spectra, obtained by inversion assuming different $d_f$ values. Inspection of these curves identifies $d_f = 49 \pm 0.5$ nm as the correct choice. The resulting $\varepsilon_f$ for the polypyrrole is shown in Figure 13 (●). The solid line results in Figure 13 were obtained in a least squares regression analysis of the same $(\Psi, \Delta)$ data assuming that $\varepsilon_f$ can be described as a sum of three Lorentz oscillators. Thus, this analysis requires extraction of 11 $\lambda$-independent parameters, ten associated with Equation (68), and one thickness. The resulting best fit $d_f$ by least squares regression was found to be $47.5 \pm 2$ nm, in good agreement with the value from artifact minimization. The agreement between the dielectric functions is also very good. Oscillators with $E_1 = 1.65$ eV and $E_2 = 2.3$ eV appear to represent sub-gap transitions from the valence band to defect states associated with anion (NO3−) doping whereas the oscillator at $E_3 = 3.8$ eV represents the band gap transition.

As another example, Figure 14 shows the optical properties, expressed in terms of the index of refraction $n_f$ and the absorption coefficient $a_f$, plotted versus photon energy for a much thinner film ($d_f = 4.1$ nm) of the protein LPO adsorbed onto a Au substrate.55 These results were obtained serially by in situ SE using

Figure 13 Dielectric function of a 49 nm polypyrrole film deduced assuming a single-layer optical model (H2O/PPy/Au) and the method of Figure 12 (●). The solid line is obtained by fitting the $(\Psi, \Delta)$ spectra using a model for the dielectric function that includes three Lorentz oscillators. ● Inversion; — oscillator model; $\varepsilon_1 = n^2 - k^2$; $\varepsilon_2 = 2nk$. (Reproduced from Y.-T. Kim, D.L. Allara, R.W. Collins, K. Vedam, Thin Solid Films, 193–194, 350–360. Copyright (1990) with permission of Elsevier Science.73)

Figure 14 Spectra of the refractive index $n$ and absorption coefficient $a$ for a 4.1 nm thick monolayer film of the protein LPO measured at the solid–liquid interface. (Reproduced from H. Arwin, Thin Solid Films, 313–314, 764–774. Copyright (1998) with permission of Elsevier Science.55)
a single-channel instrument, and were extracted from $(\psi, \Delta)$ data using numerical inversion. For such films, the correct thickness $d_1$ can be chosen to ensure first that no Au substrate-related features appear in the LPO film optical properties and second that $\alpha_l$ vanishes in the regions where absorption bands are absent. As in the case of polypyrrole, well-defined features appear in the LPO optical properties that are specific to the protein and can assist in its identification or thickness determination when the optical properties are added to a database.

Next, applications of SE for characterization of thick semitransparent films will be described. In this case, the spectra in $(\psi, \Delta)$ show interference patterns since $Z_l$ in Equation (26) passes through several periods as $\lambda$ increases from the ultraviolet to near-infrared. Figure 15 provides results for a ZnSe layer prepared by molecular beam epitaxy on GaAs. These results were obtained with a rotating analyzer instrument (see Figure 6), and the sample was mounted in an open-windowed cell for measurement. Studies of native oxide removal were performed by exposing the surface to a NH$_4$OH : CH$_3$OH solution, and then to dry N$_2$, while monitoring in real time at 3.5 eV. If no further increases in $\Delta$ were detected with additional cycling, it was assumed that the oxide was completely removed. Then the $(\psi, \Delta)$ spectra were obtained on the oxide-free, stable surfaces under flowing N$_2$. For photon energies above the bandgap where the ZnSe film is opaque, $(\psi, \Delta)$ provide $\epsilon_l$ for the ZnSe directly according to Equation (23). Below the gap where the film is nonabsorbing, a rapidly varying interference pattern dominates $(\psi, \Delta)$. In this regime, $\epsilon_l$ can be deduced by numerical inversion using a single layer model and the known $\epsilon_s$ for the GaAs substrate. In this case, the layer thickness was chosen to eliminate interference artifacts in $\epsilon_l$, leading to $d_l = 1363.3 \pm 7.6$ nm. Figure 16 shows the dielectric functions of the ZnSe along with two Zn$_{1-x}$Cd$_x$Se layers on GaAs obtained using the same methods. The solid lines are fits to these results using 27 parameters that are each quadratic functions of $x$. This parameterization allows SE data to be modeled for any Zn$_{1-x}$Cd$_x$Se layer to determine $d_l$ and $x$. Finally, the inset in Figure 16 shows the variability in the $\epsilon_{2l}$ spectra for ZnSe near the bandgap, as obtained by different researchers. This variability is attributed to the differences in the surface conditions, with the lowest $\epsilon_{2l}$ being most representative of the correct results in this case.

The analysis of the $(\psi, \Delta)$ data for the ZnSe/GaAs heterostructures of Figure 15 is relatively straightforward owing to the perfection of the structure once the oxide is removed. Here, an application at the other extreme is described, a thick transparent conducting SnO$_2$:F film prepared by chemical vapor deposition on glass. Figure 17 shows $(\psi, \Delta, R)$ of the sample and $p$ of the reflected beam for a SnO$_2$:F film plotted versus energy, measured in parallel in 2.5 s using a rotating compensator multichannel ellipsimeter. Least squares regression analysis of the $(\psi, \Delta)$ data is performed from 1.5–3.75 eV where $p > 0.9$. In the analysis, the dielectric function of the SnO$_2$:F is simulated using two oscillators, the first due to free electrons with $E_1 = 0$ eV and the second due to interband transitions with $E_2$ greater than the bandgap of SnO$_2$:F. This second oscillator is described as a convolution between a Lorentz oscillator and a Tauc law that generates a well-defined absorption onset at the SnO$_2$:F bandgap. As a result, the dielectric function of the SnO$_2$:F is defined by seven free parameters. Figure 17 includes the best fit to the $(\psi, \Delta)$ spectra, and Figure 18 shows the resulting dielectric function along

with the deduced sample structure. The latter includes a 752.4 ± 3.0 nm bulk layer and a 14.0 ± 1.6 nm surface roughness layer consisting of 0.48 ± 0.14 volume fraction of voids. The reflectance spectrum predicted on the basis of the best fit optical model for ($\psi$, $\Delta$) shows systematic deviations from the data in Figure 17. The deviations can be accounted for by assuming additional roughness that is undetectable by SE because its feature scale is too large (see section 4.4). As a result, this macroscopic roughness component generates light scattering that appears as

Figure 17 Spectra in ($\psi$, $\Delta$), the degree of polarization $p$ of the reflected beam, and the reflectance $R$ for a 0.75 µm thick fluorine-doped SnO$_2$ film on glass. All four spectra were collected in 2.5 s using the rotating compensator multichannel ellipsometer of Figure 19. The solid lines are fits to the data using the two-layer model of Figure 18, along with a macroscopic roughness layer required to fit $R$ (Unpublished data from P.I. Rovira, R.W. Collins, (1998).)

a reflectance loss. The best fit to $R$ in Figure 17 is obtained by including, in addition to the microscopic roughness layer, a macroscopic roughness layer having a 15 nm wide Lorentzian distribution for the surface profile normal to the film plane with a distribution full-width at half-maximum of 3 nm.

### 5 REAL TIME MEASUREMENT

Each of the automatic instruments in section 4.1 can be used for real time studies at a single wavelength. In this mode, minimum \((\psi, \Delta)\) measurement times range from 20\( \mu \)s to 5\( ms \). Because of the limitations in the analysis of data collected in real time at one \( \lambda \), the focus in the first part of this section will be on instruments designed for high speed SE from the ultraviolet to near-infrared. Such instruments have been designed on the same principles as the slower scanning instruments of section 4.1, namely nulling, rotating element, and phase modulation. Two different approaches are used for rapid spectral scanning. In the first approach, a rotating grating or interference filter can replace the slower stepping-motor controlled monochromator. In the second approach, a spectrograph and photodiode array for parallel SE data acquisition can replace the conventional monochromator and PMT. In sections 5.1 and 5.2, the instruments for high speed SE and the data analysis procedures unique to RTSE will be described, respectively. In sections 5.3 and 5.4, applications of these instruments will be presented.

#### 5.1 Instrument Designs and Selection

The first rapid-scanning system for RTSE has been designed based on the automatic nulling principle using Faraday cell modulators as in Figure 5.\(^{76}\) The instrument also uses a Xe source and rotating interference filter as a rapid-scanning monochromator, and a single PMT as the detector. Successive "nulling angles" are measured repetitively with an acquisition time of 1\( ms \), and related to the wavelength scan through an encoder on the interference filter. A spectrum consisting of \(~400 \lambda\) values can be measured with a 3\( s \) repetition time. The orders of magnitude difference between the single \((\psi, \Delta)\) acquisition time and the full spectra repetition times is characteristic of a serial-scanning system. The advantages of this self-nulling instrument include uniform sensitivity for all reflecting surfaces and the capability of measuring \((\psi, \Delta)\) over their full ranges without ambiguity.

A different instrument for RTSE has been developed based the rotating polarizer principle.\(^{18,34}\) Its design exploits the fact that the mechanical period accessible to a continuously rotating polarizer is \(~10\) times longer than the scanning time of a multichannel detector (5–10\( ms \)). The instrument utilizes a Xe source to generate a white light beam that is linearly polarized by a rotating polarizer and reflected from the sample. The detection system, mounted after a fixed analyzer, consists of a spectrograph and a 1024-pixel linear Si photodiode array. The 1024 pixels can be grouped by eight for 128 spectral positions. The array is operated in an integrating mode, and readout is triggered at least three times per half-rotation using an encoder output from the polarizer. This yields at least three integrals over the irradiance waveform registered at each pixel group. From a minimum of three readouts, spectra in \((\alpha, \beta)\) and \((\psi, \Delta)\) can be determined (see Equations 51 and 52). With this design, the minimum acquisition and repetition times for SE data are both equal to the polarizer optical period \(\pi/\omega\). The integrating mode implies that all pixel groups are measuring the irradiance at all times so that instrument operation is fully parallel. Thus, the rotating polarizer system has demonstrated the highest speed reported for RTSE, acquisition and repetition times of 16 and 32\( ms \), respectively, for 64 spectral points. Under these conditions, standard deviations of \(\delta\psi \leq 0.06^\circ\) and \(\delta\Delta \leq 0.12^\circ\) have been obtained at \(\lambda = 496\)\( nm \) under film growth conditions. Acquisition and repetition times of 3\( s \) have yielded \(\delta\psi \leq 0.003^\circ\) and \(\delta\Delta \leq 0.007^\circ\) at \(\lambda = 496\)\( nm \).\(^{77}\)
Figure 19 Schematic of a rotating-compensator multichannel ellipsometer.

The third and most recent rapid-scanning ellipsometer has been developed based on the phase modulation principle. With the exception of the detection system, this instrument design is similar to that in Figure 7. A Xe source and polarizer provides a white light beam whose polarization is modulated by a piezobirefringent element. As in the rotating polarizer multichannel ellipsometer, the polarization detector consists of an analyzer, spectrograph, and photodiode array (40 pixels in this case). Because the phase-modulator period (20 µs) is ~100 times faster than the array scanning time, however, the detector cannot be operated in an integrating mode. Instead, the pixel outputs are multiplexed into a common signal processor. The output of each pixel is digitized at 1 MHz, and a fast Fourier transform provides the dc component, and first and second harmonics of the irradiance waveform from which \((\psi, \Delta)\) can be determined (see Equations 61–65). The disadvantage of the multiplexing scheme is that, although the photodiode array is a parallel detector, the pixels are sampled serially. Thus, the repetition time is 40 times longer than the acquisition time.

Finally, advanced versions of the rotating element multichannel ellipsometer have been developed as well that allow high speed collection of spectra in the reflectance \(R\) and/or degree of polarization \(p\) of the beam in addition to \((\psi, \Delta)\). For the rotating polarizer multichannel ellipsometer, at least three readouts of the photodiode array every polarizer half-rotation are sufficient to obtain \((\psi, \Delta)\) and \(R\). In this case, it is necessary to measure the ellipsometer system response to obtain absolute reflectance spectra in real time studies of film growth. This is done using a starting substrate of known optical properties and structure. Finally, a rotating compensator multichannel ellipsometer has also been developed. With this instrument, \((\psi, \Delta)\), and \(R\) for the sample and \(p\) for the reflected beam can be derived from raw data collected in a time as short as 32 ms using a minimum of five readouts of the array every compensator half-rotation (see Figure 19). An application of this instrument for ex situ analysis of a transparent conducting oxide film was described in section 4.6.2.

5.2 Data Analysis

RTSE data analysis procedures follow the same principles as the ex situ analysis procedures of section 4.5. The first method, least squares regression analysis, allows extraction of the \(\lambda\)-independent parameters that describe the sample structure and optical properties at a given time during film growth or surface modification. With this approach, a database for the optical properties of one or more components of the sample may be required at the actual processing temperature of the sample. This requirement can lead to difficulties in the analysis particularly for processing in which the sample temperature changes. With the high speed data collection capability of instruments for RTSE, however, databases for materials of different composition and temperature, for example, can be established expeditiously. The second method of data analysis, exact mathematical inversion, yields the optical properties of one material as well as one or more \(\lambda\)-independent sample structural parameters characteristic of a given time in the process.

In many cases, the optical properties of one of the layers of the sample can be assumed to remain unchanged during some stage of film growth. In such cases, least squares regression and exact inversion methods can be combined in a global error function minimization procedure. First, \((\psi, \Delta)\) spectra are chosen at a specific time \(t_1\)
during the deposition of the layer. Then trial values are chosen for the structural parameters associated with this layer, e.g., bulk, surface roughness, or interface roughness layer thicknesses. Next the \((\psi, \Delta)\) spectra at \(t = t_1\) are subjected to exact inversion to deduce a trial dielectric function \(\varepsilon_i\) of the growing layer. \(\varepsilon_i\) is applied in least squares regression analysis of the \((\psi, \Delta)\) spectra collected for times \(t_0 \leq t \leq t_1\) during which \(\varepsilon_j\) is assumed to be constant. The output of the regression analysis is the time dependence of the \(\lambda\)-independent structural parameters for \(t_0 \leq t \leq t_1\). The error functions between the measured and best fit SE data, when summed for all spectra collected versus time \(t_0 \leq t \leq t_1\), provide a measure of the quality of the global fit. Finally, the initial guesses for the structural parameters at \(t = t_1\) are adjusted and the process is iterated until the sum of the error functions is minimized. Under the global best fit conditions, \(\varepsilon_i\) obtained by inversion at \(t = t_1\) is correct, and the time dependences of the structural parameters obtained by least squares regression for \(t_0 \leq t \leq t_1\) are also correct.

One might expect ideal uniform growth with thickness-independent optical properties for the preparation of heteroepitaxial crystalline films. Thickness dependences in the optical properties can occur, however, due to quantum size effects in thin layers or to strain relaxation in thicker layers. In the case of the quantum effects, the optical properties of the layer at a given time are uniform throughout the thickness, but these properties change, i.e. become more bulk-like, with increasing thickness. In the case of strain relaxation, the optical properties exhibit a gradient with thickness, such that the near-substrate and near-surface properties are characteristic of strained and relaxed material, respectively. Analogous problems occur in the deposition of nonepitaxial and noncrystalline films. The thickness dependences in the optical properties can occur in thin layers due to clustering during nucleation and to size effects. In thicker layers, the crystallite size or void fraction within the film may evolve with thickness. The optical properties during nucleation can be modeled in a similar manner to the size effects. Specifically, the layer optical properties at a given time are assumed to be uniform throughout the thickness, but these properties change continuously as the clusters increase in size and coalesce. In contrast, when structural evolution occurs in coalesced layers, the properties exhibit a gradient with thickness.

Here, analysis of RTSE data acquired during graded layer growth will be discussed. Graded layers can result from the natural structural evolution of a film (as just described) or from intentional compositional variations imposed continuously during growth. Intentional variations can be obtained in chemical vapor deposition, for example, by varying the source gas flows. The simplest graded layer analysis employs a one-layer model based on the assumption that the interface to the ambient is perfect and that a “virtual interface” exists at a depth \(d_0\) below the film surface. The virtual interface separates the most recently deposited material of thickness \(d_0\), called the outerlayer, from the underlying material which includes the past history of the deposition. Thus, the underlying material is treated as a “pseudo-substrate” characterized by a pseudodielectric function. The one-layer or pseudosubstrate approximation is exact in the limit of very thin outerlayers on opaque uniform substrate films. The goal of graded-layer analysis is to extract the deposition rate \(r_d\) and the outerlayer composition \(x_0\), assuming that a parameterization scheme exists that allows the dielectric function to be determined given \(x_0\).

The graded-layer analysis begins by considering the first \(N\) (odd) spectra \(\{\psi_m, \Delta_m; m = 1, \ldots, N\}\) collected in a time \(\delta t\) starting from \(t_0\) at which graded layer growth begins. These spectra are converted into pseudodielectric functions \(\{\varepsilon_m\}; m = 1, \ldots, N\), using Equation (23). First, trial values are chosen for \(r_d\) and \(x_0\) appropriate for the interval \(\delta t\). Then the derivative \(\langle \varepsilon \rangle\) with respect to outerlayer thickness \(d_0\), denoted \(\langle \varepsilon \rangle_{-}\) and evaluated at \(t = t_0 + \delta t/2\), is determined from \(\langle \varepsilon_m \rangle\) by a point linear regression. Next, the pseudosubstrate approximation

\[
\langle \varepsilon \rangle_{-} = \frac{4\pi i (\varepsilon_c - \varepsilon_0) (\varepsilon_0 - 1) \langle \varepsilon \rangle_c - \sin^2 \phi_0}{\lambda\varepsilon_0 (\langle \varepsilon \rangle_c - 1)}^{1/2}
\]

is applied where \(\varepsilon_0\) is the outerlayer dielectric function defined by \(x_0\). Equation (69) provides \(\langle \varepsilon \rangle_c = \langle \varepsilon \rangle_p [\mu = (N + 1)/2]\), the calculated pseudodielectric function at center \(c\) of the data collection range \((t = t_0 + \delta t/2)\), which is in turn converted into \((\psi_f, \Delta_f)\). The trial values of \(x_0\) and \(r_d\) are adjusted to minimize an error function between the measured and calculated \((\psi_f, \Delta_f)\) spectra. The overall procedure is repeated for successive \(N\)-member pairs of real time \((\psi, \Delta)\) spectra to determine the best-fit \(x_0\) and \(r_d\) versus time from which the depth profile in \(x_0\) can be deduced.

This analysis has two limitations that have been addressed in refinements and alternative approaches. First, it is assumed that the top surface of the sample is atomically smooth. In a refinement of the above procedure, a two-layer analysis has been developed that includes a surface roughness layer on top of the outerlayer. The roughness layer is modeled as a 0.5/0.5 volume fraction mixture of the outerlayer and void using the Bruggeman theory, and its thickness is determined in the analysis. The results of such a depth-profiling study for graded amorphous silicon carbon alloys is given in section 6. Second, for Equation (69) to be valid, the underlying film structure must be opaque. Thus, the procedure is not valid for graded weakly absorbing materials.
In order to handle such situations, in general, one must resort to an analysis in which film growth is divided into small segments within which the optical properties are assumed to be constant. Then, a procedure based on inversion and least squares regression can be applied.

5.3 Applications in Gaseous and Plasma Environments

In this section, the focus will be on applications of RTSE in film growth environments that preclude other real time probes used in high vacuum (see section 6). Such environments include chemical vapor deposition that utilizes relatively high pressure reactive gases. As an example, recent studies of diamond film growth by microwave plasma-enhanced chemical vapor deposition will be described. Such studies were performed using rotating-element multichannel ellipsometers, and analysis by least squares regression has provided a number of parameters of interest including (i) the near surface temperature of the substrate, (ii) the bulk layer deposition rate, (iii) the evolution of the surface roughness layer thickness, (iv) the composition of the final film, and (v) the thickness uniformity of the film over the beam area. In fact, the unique ability to deduce near surface temperature and film growth rate permits an improved understanding of the kinetics and chemical mechanisms for film growth using different gas mixtures.

Temperature measurements of the silicon substrates were performed by RTSE during their exposure to the plasmas used for diamond film growth. The induction time for diamond nucleation on the substrate was longer than the time required for the substrate to reach thermal equilibrium with the plasma. Thus, in the analysis to determine the substrate temperature $T$ a one-layer structure could be assumed, consisting of a native oxide on Si. The Si dielectric function was deduced from the $(\psi, \Delta)$ spectra using exact numerical inversion in which the oxide thickness was also determined. To obtain $T$, the second derivative of the Si dielectric function in the neighborhood of the sharp feature near 3.3 eV, reflecting the band structure critical point at $E_1$ in $k$-space, was fitted to an analytical form for an excitonic transition, namely,

$$\frac{d^2\varepsilon}{dE^2} = \frac{2A_1 \exp(\theta_1)}{(E - E_1 + i\Gamma_1)^3}$$

in order to extract the amplitude $A_1$, phase $\theta_1$, resonance energy $E_1$, and broadening parameter $\Gamma_1$. A prior study has reported that $E_1$ decreases linearly with $T$ according to $E_1(eV) = 3.375 - [4.07 \times 10^{-4}T(°C)]$, from which $T$ can be obtained by substituting $E_1$. At $E = E_1$, the absorption depth ($\alpha^{-1}$) is $\sim20\,nm$, and $\sim3\alpha^{-1}$ is the surface region from which $T$ is measured. As a result, the temperature obtained by SE is a true characteristic of the Si surface. Figure 20 shows results, in which the error $\Delta T$, i.e. the difference between the true temperature $T$ determined by RTSE and the nominal value from a thermocouple, is plotted versus $T$ for microwave plasmas at 0.5 kW power using different CO/H$_2$ gas flow ratios at a pressure of 10 Torr.

Figure 21 shows RTSE analysis results for diamond film growth using a CO/H$_2$ flow ratio of 4.7, a temperature of 375°C, and a pressure of 10 Torr. The data were collected with a rotating-polarizer multichannel ellipsometer. The substrate in Figure 21 was a diamond film with a $\sim16\,nm$ thick roughness layer prepared on a Si substrate. Because of the roughness layer on the underlying film, analysis of the RTSE data by least squares regression employed first a two-layer model [ambient/(surface roughness)/(interface roughness)/substrate] that simulates interface formation between the underlying structure and the new film, and then a three-layer model [ambient/(surface roughness)/bulk/(interface roughness)/substrate] that simulates bulk film growth. In the interface formation regime, the two free parameters include (i) the volume fraction of new diamond ($f_d$) that forms within the modulations of the substrate roughness and (ii) the thickness of the diamond layer ($d_s$) that forms above the substrate roughness. In the bulk growth regime, the four free parameters include (i) the bulk layer...
For bulk layer thicknesses \(< 30 \text{ nm}\), the bulk layer composition is fixed (broken lines in Figure 21) to ensure stability of the analysis. The results in Figure 21 are consistent with a process in which the substrate interface fills in as the diamond film roughness layer develops to \(~20\) nm. In the bulk regime, the roughness layer relaxes to \(11\) nm as the bulk layer thickness increases linearly with time at \(0.9\) nm min\(^{-1}\). In this regime, the bulk composition is stable (0.78 \(\pm\) 0.04 diamond, 0.20 \(\pm\) 0.03 void, and 0.02 \(\pm\) 0.01 sp\(^2\) C).

The analysis of Figure 21 can be performed for each of a series of diamond films deposited on the same substrate under different conditions.\(^{\text{85}}\) The results of such analyses provide the time evolution of the diamond mass thickness, i.e. the diamond volume per area, as a function of the conditions. The mass thickness is given by \(d_m = f_{db}d_b + f_{sp2}d_{sp2} + f_vd_v\), where \(f_{db}\) is the fraction of diamond within the layer of thickness \(d_b\), where \((v = i,b, s)\) designate the interface roughness, bulk, and surface roughness layers, respectively. Figure 22 shows the mass thickness rate versus the true near surface temperature for microwave plasma-enhanced chemical vapor deposition of diamond using different gas mixtures at a pressure of 10 Torr and a plasma power of 0.5 kW. When CO or CH\(_4\) is highly diluted in H\(_2\), the rate increases with \(T\) in accordance with an 8 kcal mol\(^{-1}\) activation energy (solid lines) that appears to suggest a common hydrocarbon film precursor such as CH\(_3\). As the CO/H\(_2\) ratio is increased to 18, the \(T\)-dependence of the rate is no longer activated and a sharp maximum develops near 500°C. This behavior has suggested a new diamond growth mechanism from nonhydrocarbon precursors.

thickness \((d_b)\), (ii) the surface roughness layer thickness \((d_s)\), (iii) the bulk layer void volume fraction \((f_v)\), and (iv) the bulk layer graphic or sp\(^2\) C carbon volume fraction \((f_{sp2})\). The latter undesirable component in diamond films is simulated with glassy carbon (pure sp\(^2\) C) whose dielectric function is known from a previous database.

In the two-layer film structure, the interface roughness layer is modeled using the Bruggeman theory as a two-component diamond/void composite in which the composition varies with time. This approach simulates the filling of the modulations in the roughness layer of the substrate film upon growth of the new film. In the three-layer structure, the surface roughness layer is modeled as a 50/50 vol.% mixture of [diamond + void], whereas the bulk layer is modeled as a [diamond + (sp\(^2\) C) + void] composite. For bulk layer thicknesses \(<50\) nm, the bulk layer composition was fixed (broken lines in Figure 21) to ensure stability of the analysis. The results in Figure 21 are consistent with a process in which the substrate interface fills in as the diamond film roughness layer develops to \(~20\) nm. In the bulk regime, the roughness layer relaxes to \(11\) nm as the bulk layer thickness increases linearly with time at 0.9 nm min\(^{-1}\). In this regime, the bulk composition is stable (0.78 \(\pm\) 0.04 diamond, 0.20 \(\pm\) 0.03 void, and 0.02 \(\pm\) 0.01 sp\(^2\) C).

The analysis of Figure 21 can be performed for each of a series of diamond films deposited on the same substrate under different conditions.\(^{\text{85}}\) The results of such analyses provide the time evolution of the diamond mass thickness, i.e. the diamond volume per area, as a function of the conditions. The mass thickness is given by \(d_m = f_{db}d_b + f_{sp2}d_{sp2} + f_vd_v\), where \(f_{db}\) is the fraction of diamond within the layer of thickness \(d_b\), where \((v = i,b, s)\) designate the interface roughness, bulk, and surface roughness layers, respectively. Figure 22 shows the mass thickness rate versus the true near surface temperature for microwave plasma-enhanced chemical vapor deposition of diamond using different gas mixtures at a pressure of 10 Torr and a plasma power of 0.5 kW. When CO or CH\(_4\) is highly diluted in H\(_2\), the rate increases with \(T\) in accordance with an 8 kcal mol\(^{-1}\) activation energy (solid lines) that appears to suggest a common hydrocarbon film precursor such as CH\(_3\). As the CO/H\(_2\) ratio is increased to 18, the \(T\)-dependence of the rate is no longer activated and a sharp maximum develops near 500°C. This behavior has suggested a new diamond growth mechanism from nonhydrocarbon precursors.

\(\text{Figure 21} \) Structural evolution of diamond film growth on diamond, deduced from RTSE data collected with a [CO]/[H\(_2\)] gas flow ratio of 4.7 and \(T = 375\) °C. Structural parameters include (top panel) the volume fraction of diamond within the modulations of the substrate surface roughness \((f_{db})\), the volume fractions of sp\(^2\) C \((f_{sp2})\) and void \((f_v)\) in the bulk layer, and (bottom panel) the thicknesses of the bulk \((d_b)\) and surface roughness \((d_s)\) layers. The horizontal broken lines (top panel) indicate fixed compositions. (Reproduced from J. Lee, B. Hong, R. Messier, R.W. Collins, \textit{Thin Solid Films}, 313–314, 506–510. Figure 23 shows spectra in the reflected beam degree of polarization \( p \) for the Si substrate and for selected mass thicknesses of diamond obtained using a rotating-compensator multichannel ellipsometer in real time during film growth.\(^{(56)}\) The diamond film was deposited at \( T = 812 \, ^\circ\text{C} \) with a CO/H\(_2\) flow ratio of 0.022. Upon initial nucleation of diamond, there is a significant decrease in \( p \) from unity over the higher energy range. This can be attributed to multiple scattering of the beam within the largest diamond crystallites which are on the order of the wavelength. The features in the two spectra in the thick film regime in Figure 23 can be attributed to thickness variations over the surfaces of the films. A simplified one-layer model for the film was used to simulate the spectra in \( p \), assuming a linear thickness gradient over the area probed by the beam as shown in the inset of Figure 24.\(^{(56)}\) Using this model, the probed area was partitioned into \( 2N_d + 1 \) slices having thicknesses \( d = d_{av} + M\Delta d \), where \( d_{av} \) is the average thickness, \( \Delta d = 0.3 \, \text{nm} \) is the thickness increment between slices, and \( M \) is an integer whose value ranges from \( -N_d \) to \( N_d \). Irradiance waveforms were generated for all \( 2N_d + 1 \) thicknesses using the optical properties of the media as deduced from the \( (\psi, \Delta) \) spectra along with trial values for the thickness variation, \( 2N_d\Delta d \), and the average thickness \( d_{av} \). The irradiance waveform for each thickness was weighted by the area fraction, and then all waveforms were added, assuming incoherent superposition. The calculated spectra for \( p \) were then compared with the data in an attempt to match the features. Best fit simulations are shown in Figure 23. Figure 24 includes the resulting film thickness gradient, derived from the beam diameter of 3.5 mm, versus the mass thickness. When one or more well-defined minima in \( p \) are observed, the uncertainty in the gradient is \( \pm 1.5 \, \text{nm cm}^{-1} \).

Figure 24 Diamond film thickness gradient over the area probed by the incident beam, plotted versus effective film thickness. The inset shows a schematic of the cross-section of the beam on the film surface (\( x-y \) plane) and the orientation of the assumed linear thickness gradient. Applications in Liquid Environments

Applications of RTSE will be described next for analysis of film growth and modification in liquid environments. Such environments preclude in situ probes based on conventional electron and ion spectrosopies. Although liquid ambient media often reduce its spectral range, RTSE provides sufficient sensitivity for characterizing film formation at the monolayer level as well as small changes in the composition of bulk materials (±0.2 vol.%). Most applications of RTSE for studies of surfaces in liquids are in the field of electrochemistry and involve research into processes of adsorption, oxidation, passivation, corrosion, polishing, and deposition. Here, three applications are described, including electrodeposition of lead on a copper substrate, electrochemical oxidation of a silver crystal surface, and electrochromic reduction of WO₃.

The first application of RTSE using the rapid scanning, self-nulling instrument was for studies of plating additives in electrodeposition. Figure 25 shows RTSE data plotted versus \( \lambda \) for potentiostatic deposition of Pb on a polycrystalline Cu electrode. An aqueous electrolyte containing Pb(NO₃)₂ and NaClO₄ without additives was used for electrodeposition and each pair of spectra in (\( \psi, \Delta \)) was collected in 3s. The values (0, 31, 60, 110) alongside the curves in Figure 25 represent the expected thicknesses (in nm) of the Pb film as measured by coulometry, i.e. by charge balance assuming a film of single crystal density. An analysis of the RTSE data, however, found that this was not the true physical thickness of the layer due to a complicated, porous...
microstructure. The inset in Figure 25(a) shows the optical model that provides the best fit to the data. This model includes (i) a compact layer of Pb at the substrate interface, (ii) a porous Pb layer with optical properties computed as a mixture of bulk Pb and electrolyte using the Bruggeman theory, and (iii) islands of Pb at the top surface whose optical effect is calculated as a coherent superposition of two polarization states from surface elements with and without island coverage. Overall, the best fit model results were found to be in good agreement with the data and consistent with coulometry and scanning electron microscopy. Since the coverage of the porous layer by islands was found to be low (~5–10%) and the size of the islands was <10µm, the optical effect of this layer on the polarization was much weaker than the other layers (see section 4.4). The values in parentheses alongside the data and fits in Figure 25(b) are the best fit thicknesses (in nm) of the compact and porous layers, and the volume fraction of Pb in the porous layer, respectively. From the information on the distribution of Pb between compact, porous, and island structures, the effect of plating additives could be characterized in detail.

The same instrument for RTSE was also used to study initial oxidation of Ag(111) surfaces to the Ag₂O phase upon application of a potential step. Oxidation was performed in an aqueous electrolyte with KOH, and each pair of (ψ, Δ) spectra consisting of 40 points was collected in 3.5 s. The optical model found to provide the best overall fit to the RTSE data is shown in the inset of Figure 26(b) and consists of a dense oxide film (primary layer) at the interface to the Ag, modeled as a homogeneous layer, and a surface layer of crystalline nuclei (secondary layer) modeled assuming coherent superposition. In Figure 26(a) and (b), the evolution
of the two layer thicknesses are shown versus time after application of the potential step. The thickness of the dense oxide layer initially increases, but decreases sharply at the onset of crystallite nucleation. This suggests that oxide crystallites nucleate at sites within the dense layer and then oxide mass is redistributed by dissolution of the dense layer, followed by precipitation at the crystallites. Figure 27 shows the time dependence of the crystallite number density on the surface. These results can be derived from the crystallite layer thickness and surface coverage, assuming hemispherical crystallites. The behavior in Figure 27 also appears to be another manifestation of dissolution and precipitation via an Ostwald ripening phenomenon. Through these studies RTSE has shown that the oxidation process is more complex than had been previously proposed.

In the electrochromic effect for WO₃, the optical properties of the material immersed in an electrolyte are altered by dual injection (“coloring”) or emission (“bleaching”) of electrons and ions. Figure 28 shows RTSE data collected using a rotating-polarizer multichannel ellipsometer (with acquisition and repetition times of 0.2 s and 1 s) during three 82 s color–bleach cycles for a 15 nm WO₃ film prepared on a Cr contact layer by sputtering. The electrolyte was an aqueous solution containing H₂SO₄, and the coloring voltage was applied for 1 s and held for 40 s. From these data, the dielectric function for the bleached state (WO₃) can be deduced by exact inversion using a single-layer model in which the thickness is chosen to ensure that ε₂ = 0 in the visible as shown in Figure 29. The dielectric function for the colored state (HₓWO₃₋ₓ) in Figure 29 is obtained assuming that the thickness does not change upon coloring. Using these results, the kinetics of coloring can be determined as shown in Figure 30. In this figure, the correct kinetic model is identified from the evolution of the error function, computed in this case as the unbiased estimator of the mean square deviation between the experimental and best fit (tan ψ, cos Δ) spectra. In the diffusion model, a colored layer in contact with the electrolyte is assumed to increase in thickness at the expense of the underlying bleached layer. The interphase between the layers represents the diffusion front of H⁺ ions that react with electrons in WO₃ to form tungsten bronze, HₓWO₃₋ₓ. In the reaction-limited model, a composite of the colored (HₓWO₃₋ₓ) and bleached (WO₃) phases is assumed to exist in which the optical properties of the composite are calculated from the Bruggeman theory. The better agreement with a reaction limited model is consistent.

![Figure 29](image1.png) **Figure 29** Dielectric functions of a 15 nm electrochromic WO₃ film in the bleached (○) (WO₃) and colored (●) (HₓWO₃₋ₓ) states, obtained from a one-layer analysis of the RTSE data (see Figure 28). with a mechanism whereby coloring is limited by diffusion of ions parallel to the film plane from void channels that extend throughout the film.

6 COMPARISON WITH OTHER TECHNIQUES

Ellipsometry in its various forms is used most widely to determine film thicknesses from partial monolayer coverage of a substrate surface (~0.01 nm) to thick coatings (~10 µm). The uniqueness of ellipsometry is its ability to perform such measurements in situ and in real time with the sample immersed in any medium that is transparent to the incident beam. It should be recalled, however, that the entire optical problem must be solved (i.e. the dielectric functions of all the media must be known or determined) in order to obtain accurate thickness values. Several alternative techniques are also available for both ex situ and real time thickness measurement.

Among ex situ measurements, stylus profilometry is the most widely used method for film thickness determination owing to its simplicity. Because it can provide thickness without the need to extract other information, nonideal and non specular thin films can be measured. Furthermore, it can be used when optical measurements of opaque films fail. A disadvantage of profilometry is that it cannot provide accurate thicknesses less than about 5 nm, and even for uniform films >10 nm, ellipsometry under optimum conditions is more than an order of magnitude more accurate. In addition, an abrupt step must be generated on the sample surface; thus, profilometry can be considered an invasive or destructive method. Cross-sectional transmission electron microscopy (XTEM) or edge-on scanning electron microscopy can also be used as a destructive method of thickness determination. The advantage of microscopy is that it provides a direct image; the disadvantage is the time-consuming sample preparation. As an example, Figure 31 shows the agreement between XTEM and SE analyses of the layered structure of an ion-implanted Si wafer.91,92 Nondestructive optical techniques that do not rely on polarization state measurements can also be applied to determine film thicknesses. Transmittance and reflectance spectroscopy can be used; however, for optically thin films (\( nd \ll 1 \)), transmittance is insensitive to the presence of the film. In this case, reflectance alone cannot provide sufficient information to solve the entire thin film problem unless the optical properties of the film are known.

Alternative techniques are also available for in situ and real time thickness measurements. The most widely used is the quartz crystal oscillator that measures mass accumulation during film growth. The advantage of this method is that it yields the mass accumulation at the monolayer level without the need to extract other information. The disadvantage is that the measurement is performed for deposition on the quartz oscillator surface, not on the substrate of interest. For cases in which film growth rates are sensitive to the substrate, the usefulness of the oscillator method is limited. In

![Figure 31](https://example.com/fig31.png)

**Figure 31** Comparison of (a, b) XTEM and (c) ex situ SE analysis of a Si wafer implanted with 80 keV Si ions at a rate of 160 mA cm\(^{-2}\) with a total dose of \( 1 \times 10^{16} \text{cm}^{-2} \). OPD designates the maximum optical penetration depth accessible by SE. c-Si and a-Si designate the crystalline and amorphous phases of silicon and the subscripts indicate the volume fractions of the phases (Reproduced with permission of the American Institute of Physics from K. Vedam, P.J. McMarr, J. Narayan, *Appl. Phys. Lett.*, 47, 339–341 (1985)).92)
addition, one may be interested in the physical thickness, which is different from the mass thickness deduced by the oscillator, owing to film porosity. In contrast, SE can provide the physical thickness as well as microstructural information. Another disadvantage of the oscillator method is that it cannot be used in reactive, high pressure environments such as exist in plasma-enhanced chemical vapor deposition. A second popular real time technique for determining film thickness is reflection high energy electron diffraction. This technique is used widely to characterize monolayer-by-monolayer growth of single crystal layers in UHV, however, it fails for noncrystalline materials and at high pressures. Finally, reflectance can also be used for determining film thickness evolution in real time. This method is advantageous because of its simplicity; however, it is less sensitive than ellipsometry for monolayer level films and the information on the optical properties of the deposited material is limited. The sensitivity of reflectance can be enhanced by using a p-polarized incident beam at an angle of incidence equal to the pseudo-Brewster angle.

As has been made clear in sections 4.5 and 5.2, the usefulness of ellipsometry is not restricted to bulk film thickness determination. This technique can also provide information on roughness, structure, composition, and temperature. Detailed comparison of alternative techniques for these characteristics is beyond the scope of this discussion; however, general comments are in order. For determining surface roughness and bulk film microstructure, ellipsometry is an indirect method and is often described as model dependent because the analysis results depend on which effective medium theory is applied. Thus, it is prudent to corroborate the results using an alternative technique. As an example, Figure 32 shows the correlation between the surface roughness layer thickness deduced by RTSE at the end of film deposition and by AFM ex situ after deposition (the latter expressed as the root mean square roughness). The same set of amorphous silicon–carbon alloy films were used for both measurements. A good linear correlation is observed, particularly for microscopy performed in the tapping mode, indicating that the SE-determined roughness thickness is 1.5 times larger than the rms roughness. Such results promote confidence in the RTSE method for situations in which AFM cannot be applied, such as for characterization of the roughness evolution during deposition. Other parameters deduced by SE using indirect methods, such as the bulk film void volume fraction, may be difficult to corroborate by alternative techniques. In this case, special efforts must be undertaken to ensure that the effective medium theory is valid, e.g. by collecting SE data over the widest possible spectral range and selecting the theory that provides the best fit.

![Figure 32](image_url)

**Figure 32** Surface roughness measurements for a-Si<sub>1-x</sub>C<sub>x</sub>:H films on c-Si (<i>d</i><sub>e</sub> &lt; 35 Å) and SnO<sub>2</sub>:F (> 70 Å) substrates. Roughness layer thicknesses were deduced independently from analyses of RTSE data <i>d</i><sub>s</sub> (SE) and ex situ atomic force microscopy images <i>d</i><sub>rms</sub> (AFM) for the same samples. AFM images were obtained with microscopes operated in contact (●) and tapping (○) modes. (Reproduced with permission of the American Institute of Physics from J. Koh, Y. Lu, C.R. Wronski, Y. Kuang, R.W. Collins, T.T. Tsong, Y.E. Strausser, Appl. Phys. Lett., 68, 1297–1299 (1996).<sup>93</sup>)

In contrast to composites in which effective medium theory can be applied, mixtures on the atomic scale (i.e. alloys) cannot be analyzed by ellipsometric methods to determine composition directly. For alloys, a series of samples must be measured first using X-ray diffraction or electron spectroscopy to obtain the composition and second using SE to obtain the optical properties. Then the dielectric function (or its derivatives) can be expressed analytically in terms of <i>λ</i>-independent parameters that in turn can be described as quadratic functions of composition. Only with such a database, can SE be applied as a routine analytical tool for alloy composition. As an example, Figure 33(a) provides the depth-profile in the composition <i>x</i>, deduced from RTSE data for a graded amorphous silicon–carbon alloy (a-Si<sub>1−x</sub>C<sub>x</sub>:H) prepared by plasma-enhanced chemical vapor deposition using SiH<sub>4</sub> and CH<sub>4</sub> gases.<sup>94</sup> The graded layer is obtained using a triangular-shaped profile for the gas flow ratio <i>z</i> = [CH<sub>4</sub>]/([SiH<sub>4</sub> + CH<sub>4</sub>]) versus time. Also shown in Figure 33(a) is the result of a simulation based on reactor modeling. Good agreement between the simulation and data supports the validity of the analysis, based on Equation (69). For further corroboration, Figure 33(a) also includes a depth-profile for the same sample deduced in an ex situ destructive analysis by SIMS. SIMS yields a broader profile as a result of the
limited resolution generated by the sputtering process used for depth-profiling. In Figure 33(b), the SIMS result is compared with a RTSE depth-profile Gaussian broadened by 44 Å. The excellent agreement provides further support for the validity of such SE analyses.

7 METHOD DEVELOPMENT

Although ellipsometry is a century-old analytical technique, most applications described here have become possible as a result of instrumentation advances since the late 1980s. Several of the most notable advances will be enumerated here. (i) The incorporation of linear photodiode array detectors into ellipsometers enable high-speed parallel spectroscopy. As a result RTSE from the ultraviolet to near-infrared can be employed to characterize thin film growth dynamics and spectroscopic ME can be employed for high resolution mapping of static surfaces. (ii) The incorporation of CCD cameras into ellipsometer designs enable imaging of surfaces at high resolution for real time studies of selective adsorption, deposition, oxidation, and corrosion. (iii) The development of higher speed instrumentation for use in the infrared range allows researchers to characterize the dynamics of surface reactions with a chemical specificity not possible from measurements in the ultraviolet to near-infrared range. (iv) The determination of other parameters in addition to the angles (θ, Δ), such as the reflectance and the degree of polarization, can assist in studies of complex nonideal surfaces. (v) Finally, the last decade has seen numerous advances in data analysis capabilities to accompany the new measurement capabilities. Characterization of complex samples using ellipsometry, although not routine, is now possible, including those samples that exhibit anisotropy, structural inhomogeneity and compositional gradients throughout the thickness, nonuniformity over the beam profile, and light scattering due to structure on the scale of the wavelength.

In the absence of unforeseen new directions in the field of ellipsometry, the limitations encountered in these recent advances are expected to set the focus for future developments. (i) Ellipsometers employing photodiode arrays will benefit from improvements in multichannel detector technology that will provide higher sensitivity, thus, enabling measurements of higher quality over a wider spectral range. Furthermore, the future may see a joining of multichannel ellipsometric and near-field microscopic techniques for much higher resolution in spectroscopic ME. (ii) Continuous advances in the speed of CCD cameras and associated software for image processing are expected to lead to improvements in IE. Thus, incorporation of a rapid scanning monochromator into the imaging ellipsometer may be possible for real time spectroscopic IE. Such anticipated advances are confined to the ultraviolet to near-infrared spectral range. (iii) Advances in measurement capability in the infrared range, desirable due to the chemical bonding information available, pose even greater challenges owing to the insensitivity of detection systems. In this case, brighter sources such as provided by free electron lasers are expected to make the greatest impact. (iv) Advances in multiparameter approaches may culminate with the development of a multichannel ellipsometer that provides spectra in the 16 elements of the sample’s Muller matrix.
The Muller matrix provides a complete description of the effect of the sample on an incident polarization state of arbitrary Stokes vector. Finally, future advances in data analysis are expected to exploit continued improvements in computational speed for the application of conventional data analyses in real time monitoring and control. Improved databases and more efficient algorithms are also expected for carrying out such analyses.

section deals with some problems commonly encountered in the study, e.g. low detection sensitivity, surface heating and damage by laser, fluorescence elimination, coupling with transient measurement, and spectral data analyzing. Applications are exemplified on extensively studied areas such as in advanced materials, catalysis, electrochemistry, corrosion, biology and sensor. Finally, prospects and further developments of this field are given with emphasis on the emerging as well as promising methodologies in view of surface preparation, instrumentation and hyphenated techniques.

1 INTRODUCTION

1.1 Vibrational Properties of Surface Species

The vibrational properties of surface species are significantly different from that of the same species in bulk phases. The individual molecules may be distorted and their symmetry altered as compared to the free molecules, thus leading to modifications of their vibrational behaviors. There are various processes contributing to the bandwidths, intensities and positions, including change in molecular symmetry, dipole coupling, inhomogeneous broadening, intramolecular vibrational relaxation, dephasing, electron–hole pair creation, and phonon coupling. It is necessary to first briefly describe some key features of a molecule interacting (or adsorbing) with a surface and/or with the same or other surface species, in terms of molecular symmetry (1) dipole coupling interactions (2) and the electrochemical Stark effect (3).

A systematic and good illustration requires a model molecule as adsorbate interacting with a surface. There are several important reasons for using carbon monoxide (CO) as an adsorbate. CO possesses a minimum internal vibrational mode and can easily be isotopically labeled at either end. Besides, the $\nu_{CO}$ band position and shape are sensitive to the chemical and electrostatic environment as well as to the mode of surface bonding. The relatively large dynamic dipole moment of the $C=O$ vibration, $\nu_{CO}$, for chemisorbed CO, facilitates its detection by surface IR spectroscopy. The strong chemisorption found on transition metals enables adsorbed CO to be examined over a wide range of coverage, and under ambient and higher temperatures. Moreover, a rich base of knowledge about CO adsorption at well-defined metal surfaces in UHV can be used to probe the additional complexities of catalysts’ surfaces and electrochemical interfaces.

1.1.1 Molecular Symmetry of Surface Species (1)

It is well known that the number of dipole active vibrations of a molecule is determined by degrees of vibrational freedom and symmetry. The freedom of the molecule depends on the molecule’s physical state. A free molecule with $N$ atoms has $3N$ degrees of freedom, with $3N - 6$ ($3N - 5$ for a linear molecule) degrees of vibrational freedom. When a molecule becomes attached to the surface, the translational motion and rotational motion are restricted and the degree of vibrational freedom equals $3N$. That means, an adsorbed molecule has an excess of $6$ (or $5$) degrees of vibrational freedom. To illustrate what can happen when gaseous species adsorbed on the surface, let us consider CO adsorbed on a single crystal (1 0 0) surface. CO can adsorb either linearly or by bridge mode on the adsorption center of the surface, or both, see Figure 1. Linearly adsorbed species belong to the $C_{4v}$ point group with two totally symmetric vibrational modes belonging to the $A_{1}$ representation; one corresponds to the stretching mode of free CO molecule, another comes from the restricted translational motion of the whole CO molecule relative to the surface, i.e. the stretching mode of the surface atom with the C atom. All other four modes are twisted vibrations, are parallel to the surface and belong to the degenerate $E$ representation. The freedom for these vibrations comes from the restricted molecular translation and rotation. The bridge-bonded species has $C_{3v}$ symmetry, with two $A_{1}$ stretching modes perpendicular to the surface. The degeneration of the parallel mode as in the case of the on-top mode leaves two $B_{1}$ modes parallel to the bridged plane and two $B_{2}$ modes normal to the bridged plane (the molecular models for the $B_{2}$ vibrations are given as side views in Figure 1).

![Figure 1 Possible structural features (vibrational modes) of CO on a metal surface: (a) on-top site; (b) bridge site.](image-url)
1.2 Dipole Coupling

In an adsorbed layer at surfaces, electrostatic interactions between the dipoles induced in neighboring molecules serve to couple together the molecules’ vibrational motion. The effects of such dipole coupling interactions have been investigated in considerable detail on single crystal surfaces. Briefly, coupling has two important consequences: coupling between identical molecules gives rise to a single IR-active mode, having a vibrational frequency somewhat higher than that of the isolated single molecule; coupling between two species with different singleton frequencies yields two active modes. Each of these has a vibrational frequency close to that of the original species, so there are no significant shifts in the positions of the absorption bands. There is, however, a characteristic transfer of intensity from the low frequency mode to its higher frequency counterpart.

1.1.3 Electrochemical Stark Effect

Spectra of adsorbed species on an electrode are often characterized by changes in their vibrational frequencies with potential. Two mechanisms have been proposed in an effort to explain this shift in band position with potential:

1. The first involves molecular orbital consideration, in which electrons can be donated from filled adsorbate orbitals of proper symmetry to empty metal orbitals through σ overlap. The metal can then back-donate electrons from filled d orbitals to empty π* adsorbate anti-bonding orbitals. The frequency of an adsorbed moiety (with respect to solution species) will decrease if the π-bonding interaction dominates (such as CO), while the frequency will increase if the σ interaction is more important (as in the case of CN⁻). When the electrode potential is made more negative, the adsorbate–metal bond is weakened, owing to charge donation from the metal into adsorbate π* orbitals, thus the frequency shifts to lower wavenumber and vice versa.

2. The second is the electric field mechanism that involves coupling of highly polarizable electrons of the adsorbate with the strong electric field across the electrochemical double layer. If the electrolyte concentration is high enough (ca. 1 mol L⁻¹), most of the potential drop will be approximately linear with distance and will occur within a few angstroms of the electrochemical interface. An adsorbed species can act as a dielectric across which the largest portion of the potential drop will occur. Very high electric field (on the order of 10⁷ V cm⁻¹) is predicted to exist in the double layer. Interaction of this electric field with the dipole moment of an adsorbed molecule can lead to changes in the molecular vibrational frequency.

1.2 Surface Selection Rules for Infrared and Raman Spectroscopies

As vibrational properties of surface species are so different from that of the same species in the bulk phase, surface selection rules are extremely important for analyzing surface IR and surface Raman spectra correctly. These rules can be the basis of a valuable technique for the determination of the molecular orientation and conformation on surfaces.

1.2.1 Surface Selection Rule of Infrared Spectroscopy

The special properties of the reflection of electromagnetic radiation from metal surfaces in the IR region make it possible to obtain information about the orientation of molecular species at the interface. When the IR light is reflected from a metal surface, s-polarized radiation (whose electric field vector component is polarized perpendicular to the plane of incidence) undergoes a phase shift of nearly 180° at all angles of incidence. The incident and reflected waves cancel at the surface, giving rise to a standing wave that has a node near the surface. p-Polarized IR radiation (whose electric field vector component is parallel to the incidence plane) undergoes a phase shift that is a function of the angle of incidence. A phase shift of about 90° is attained at a glancing angle of incidence, and a standing wave that has measurable amplitude near the surface results from the interaction of incident and reflected light. Amplitude and angle of incidence relationships for interfaces with known optical parameters may be obtained by solving Fresnel’s equations.

Since p-polarized light is the only component of IR radiation with appreciable field strength at the metal surface, it alone carries information on vibrations of surface species. Greenler was the first to propose the p-polarized IR radiation carrying virtually all of the vibrational absorption information of species adsorbed at a metallic reflecting surface. Since the electric field intensity increases sharply with angle of incidence up to near grazing (for p-polarized radiation), the absorbance by an oscillator could be expected to increase as well. The absorption of radiation by an oscillator varies as the square of the cosine of the angle between the electric field vector of the radiation and the oscillating dipole. Hence, optimal absorption is obtained when the component of the dipole derivative with respect to the normal coordinate of an absorbing species is in the same direction as incident p-polarized radiation. If the IR beam is incident at very glancing/grazing angles, a sizeable component of the electric field will lie in a direction perpendicular to
a metal surface, see Figure 2(a). Oscillators with their dipole derivative component more parallel to the surface will have smaller probability of IR absorption. In this way the relative intensities of IR absorption bands can give information regarding molecular orientations on the surface. This distinction between absorbances due to oscillators oriented parallel and perpendicular with respect to the surface is known as the surface selection rule.

To summarize, for the absorption of light wavenumber $\nu$ by a molecule immobilized at a metal surface using the reflection mode, three conditions must be met: (i) the molecule must have a nonzero transition dipole moment at $\nu$; (ii) the magnitude of the mean-square electric field at the interface must be nonzero (with conditions for high detectability at large angles of incidence and p-polarized light); (iii) the transition dipole moment must have a component oriented along the surface normal.

In the case of transmission mode, see Figure 2(b), the molecular monolayer investigated is deposited uniformly onto a flat and IR transparent substrate such as CaF$_2$. Since both the p-polarized and s-polarized light is parallel to the surface, oscillators with their dipole derivative component more parallel to the surface will have larger probability of IR absorption. Based on the surface selection rule, the combined study of IR transmission spectroscopy and reflection–absorption (RA) spectroscopy can provide detailed structural information about molecular orientation of films and adsorbed layers at the surface after considering that in RA spectroscopy, vibrational modes with their transition moments perpendicular to the surface are enhanced in the reflectance spectrum. An example to determine the molecular orientation of the alkyl chains of a Langmuir–Blodgett (LB) film of an amphiphilic polymer, was shown in Figure 2(c) and (d). The intensities of CH$_2$ symmetric and antisymmetric stretching bands
INFRARED AND RAMAN SPECTROSCOPY IN ANALYSIS OF SURFACES

(5) 2.2 Surface Selection Rule of Raman Spectroscopy

For extending the surface selection rule to Raman spectroscopy of metal surfaces, let us consider a molecule placed at a flat surface. The molecule illuminated by the incident light at a certain angle can be thought to be illuminated by two beams, a direct beam and one reflected beam at the surface, which superimpose coherently at the molecule. It is shown that the molecule could be polarized by the local electric field on a flat surface and the induced dipole of the molecule radiates the scattered light. The relationships between the local electric field caused by the incident and reflected light and the scattered light can be described by a polarizability tensor, which contains nine components, such as \( \alpha_{xx}, \alpha_{yy}, \alpha_{zz}, \alpha_{xy}, \alpha_{xz}, \alpha_{yz}, \alpha_{yx}, \alpha_{zx}, \) and \( \alpha_{zy}. \) The polarizability tensor is written as follows:

\[
\alpha = \begin{pmatrix}
\alpha_{xx} & \alpha_{xy} & \alpha_{xz} \\
\alpha_{yx} & \alpha_{yy} & \alpha_{yz} \\
\alpha_{zx} & \alpha_{zy} & \alpha_{zz}
\end{pmatrix}
\]

in which \( \alpha_{xy} = \alpha_{yx}, \alpha_{xz} = \alpha_{zx}, \alpha_{yz} = \alpha_{zy}. \) Therefore there are only six independent tensor elements. The intensity of the Raman scattering light on the surface is directly related to the derivative of the polarizability tensor with respect to the given normal coordinates. In order to determine these tensor elements, it is necessary to consider the system including the molecule and surface atoms, and to define the Cartesian coordinate axis \( z \) along the surface normal and others along the surface parallel.

Based on the above statement of the molecule–surface system and coordinate frame, one is able to determine the symmetry point group of the molecule adsorbed on the surface. However, it should be emphasized that for a chemisorbed molecule, the symmetry of the point group is that of the surface molecule, possibly having a lower symmetry than the molecule in the bulk phase such as of the solution. In particular, for the strongly chemisorbed molecule, its geometry may be changed significantly by the interaction between the molecule and the surface. After obtaining the symmetry point group of the adsorbed system, it is easy to determine which symmetry representations of the vibrations of the molecule will be Raman active by looking in the group character tables for the given point group. The symmetry representations appearing in the character tables form the irreducible representation of the point group. Different vibrational modes of the molecule belong to different irreducible representations of the point group to which it belongs. Raman-active modes are those that possess nonzero components of the Raman polarizability tensor. In general, modes belonging to different representations will have different components of the nonvanishing polarizability tensor.

The surface Raman spectrum can be significantly different from the ordinary Raman spectrum. It is reasonable that the tangential component of the surface electric field is nearly zero due to the superimposition of the incident field with an out-of-phase reflected field, while the normal component of the incident field is reinforced by the reflected field. So the field component normal to the surface has an important contribution to totally symmetric vibration modes. Accordingly, it is possible to design Raman experiments such that the directions of the incident and scattering light and their polarization directions are chosen so as to enable the determination of the particular polarizability tensor elements from the observed Raman intensities, which are related directly to the surface orientation of the molecule. In addition to metals, the surface selection rules should apply to insulators at frequencies where they have metallic reflectance.

1.3 Surface-enhanced Raman Scattering and Surface-enhanced Infrared Absorption

The most important component of any reliable and general surface analytical method is the sensitivity, which is unfortunately the disadvantage of both IR spectroscopy and Raman spectroscopy in comparison with EELS and many other surface techniques. Raman scattering is a second-order process, with very low cross-sections. In the absence of any resonance Raman process, the differential Raman cross-sections \( (d\sigma/d\Omega)_{\text{RNS}} \) are smaller than \( 10^{-29} \text{ cm}^2 \text{ sr}^{-1}. \) The corresponding surface Raman intensities expected for a monolayer of adsorbates are less than \( 1 \text{ count s}^{-1} \) when using standard Raman spectrometer systems. Not surprisingly, there was no attempt to apply Raman spectroscopy to adsorbates at surfaces until the mid-1970s, when SERS was discovered.

In 1977, it was discovered largely through the work of Fleischmann, Van Duyne, Creighton, and their co-workers that molecules adsorbed on electrochemically roughened silver surfaces produce a Raman spectrum.
that is at times a millionfold more intense than what is expected. This tremendous effect was dubbed SERS. SERS differs in a number of ways from ordinary Raman spectroscopy of molecules and even from unenhanced surface Raman spectroscopy. A large number of experimental characteristics of SERS have been discovered, and the key features are summarized as follows:

1. SERS occurs for a very large number of molecules adsorbed on or near to the surface of metals in a variety of morphologies. The largest enhancements (with surface enhancement factor (SEF) > 10⁶) are observed from a few coinage metals of silver, gold and copper. An enhancement as high as 10¹⁴ is obtained from single silver nanoparticles of suitable size (see below). Little work has been reported on the alkali metals. Recently, it has been confirmed that transition metals such as Pt, Pd, Ru, Rh, Ni, Co and Fe have surface enhancements, although relatively weak. Their SEF values range from 10² to 10⁴, depending on the nature of the metal and surface roughness.

2. A surface roughness with features of submicroscopic dimensions (about 20–500 nm) and/or atomic scale roughness (adatoms, steps, kinks, or vacancies) is required. The largest enhancements occur for surfaces which are rough at the nanoscale (20–150 nm). These mainly include electrode surfaces roughened by one or more oxidation–reduction cycles (ORCs), surfaces roughened by chemical etching in acids, island films deposited on glass surfaces at elevated temperatures, films deposited by evaporation or sputtering in vacuum onto cold (100 K) substrates or by electrochemical deposition in solutions, colloids (especially aggregated colloids) generated by chemical method or laser ablation, single nanoparticles filtered from the colloids, and nanoparticle and nanorod arrays prepared by lithographic or template techniques. It has been thought that surface roughness, either atomic scale or nanoscale, was required for a strong SERS effect. However, recent results show that roughness is not a requirement for some specific molecules.

3. SERS is interface-sensitive. Molecules adsorbed in the first layer at the surface show the largest enhancements. However, the enhancement also has a long-range aspect with molecules separated from the surface by tens of nanometers showing some enhancement, depending upon the substrate morphology and physical environments.

4. The Raman bands from rough surfaces of SERS activity are completely depolarized unless single nanoparticles are employed, in contrast to those taken from molecules adsorbed on atomically smooth surfaces. Overtone and combination bands are not prevalent. Selection rules are relaxed resulting in the appearance of normally forbidden Raman modes in the surface spectra. SERS active surfaces also display a continuum inelastic background scattering and are very effective in quenching fluorescence.

5. The excitation profile (scattering intensity versus exciting frequency) deviates from the fourth-power dependence of normal Raman scattering. Both vibrational band frequencies and SERS intensities are a function of the applied electrode potential in electrochemical experiments, and the functionality may be different for different sets of vibrational modes.

Based on the experimental evidence, a number of SERS mechanisms have been proposed to explain the experimental characteristics; however, no one mechanism can explain all of the observed characteristics. There are at least two major types of mechanism that contribute to the SERS effect: an electromagnetic effect associated with large local fields caused by electromagnetic resonance; and a chemical effect involving a scattering process associated with chemical interactions between the molecule and the metal surface. In addition to the chemical effects, there are other synonyms to describe the nonelectromagnetic mechanism such as charge transfer, short-range effect and SERS-active sites.

1.3.1 The Electromagnetic Effects in Surface-enhanced Raman Scattering

Electromagnetic effects have been extensively studied and can be further divided into several enhancement processes. A major contribution to the electromagnetic enhancement is made by surface plasmons for the coinage metals. The electromagnetic field of the light at the surface can be greatly enhanced under conditions of surface plasmon excitation (collective electron resonance). At the plasmon frequency, the metal results in large field-induced polarizations and thus large local fields at the surface by the incident radiation. These local fields increase remarkably the Raman scattering intensity of the surface species, which is proportional to the square of the applied field. The rough surface not only enhances the incident laser field but also the Raman scattered field, therefore, the overall enhancement of the Raman intensity scales roughly the four orders of magnitude of the field.

Electromagnetic enhancement mechanisms are characterized by the following features: the effects are long range in nature, since the dipole fields induced in polarizable
metal particles vary as the inverse cube of the distance to the center of the particle; electromagnetic effects are generally independent of the adsorbed molecule; the enhancements depend on the electronic structure of the substrate and the roughness of the surface, since the frequency of the surface plasmon resonance depends on these factors.

Finally, it should be noted that surface plasmons are not the only sources of enhanced local electromagnetic fields. Other types of electromagnetic field lie near high-curvature points on the rough surface, e.g. Fresnel reflection effects and the “lightning rod” effect. They may become the major contribution to the enhancement for transition metals.

1.3.2 The Chemical Effects in Surface-enhanced Raman Scattering(10)

The chemical effect is associated with the electronic structure (state) of metal and adsorbate, which leads to resonance Raman scattering through photon-driven charge-transfer processes. In the charge-transfer model, an electron–hole pair of the metal is created by the incident photon, then the electron or hole is excited and tunnels into a charge-transfer excited state of the adsorbed molecule. In the first case it results in the negative ion (adsorbate molecule-electron) having equilibrium geometry differing from that of the original adsorbate molecule. Therefore, the charge-transfer process induces a nuclear relaxation in the adsorbate molecule which, after the return of the electron to the metal, leads to a vibrationally excited neutral molecule and to emission of a Raman-shifted photon. Additional Raman enhancement for adsorbates at special active sites of atomic-scale roughness may facilitate charge-transfer enhancement mechanisms, i.e. the electron–phonon couplings are increased by microscopic surface roughness features (adatoms).

In general, the chemical effects contribute to SERS on a short-range molecular scale. This mechanism depends on the adsorption site, the geometry of bonding, and the energy levels of the adsorbate molecule. For specific adsorbate–surface systems, the enhancement may be large. The contribution of charge-transfer processes to SERS has been estimated to be approximately $10^{-10}$.

1.3.3 Calculation of the Surface Enhancement Factor(7,12)

The calculation of the SEF is very important to the study of the SERS mechanism and SERS applications. It is calculated generally by comparing the integrated Raman intensity obtained from the surface with that from the solution phase. Thus, the SEF can be defined by Equation (1):

$$G = \frac{I_{surf}/N_{surf}}{I_{bulk}/N_{bulk}}$$  (1)

where $I_{surf}$ and $I_{bulk}$ denote the integrated intensities for the strongest band of surface and solution species, respectively, which can be obtained directly from Raman measurement, and $N_{surf}$ and $N_{bulk}$ represent the number of the corresponding surface and solution molecules effectively excited by a laser beam.

$N_{surf}$ can be calculated from Equation (2) after considering the contribution of surface roughness:

$$N_{surf} = \frac{RA}{\sigma}$$  (2)

where $R$ is the roughness factor of an electrode, $A$ is the area of the focal spot of the laser, and $\sigma$ is the surface area occupied by an adsorbed molecule (this may be obtained for a model molecule by other techniques, such as temperature-programmed desorption, and the electrochemical and radiotracer methods).

The calculation on $N_{bulk}$ is complex and should be considered very carefully in order to obtain the correct value. Because confocal Raman microscopy is getting more popular, the calculation of SEF based on the confocal system is given here. Figure 3(a) shows the waist profile of the laser beam of Raman microscopy and (b) the integrated intensity–depth profile of solution species along the laser waist. The plane at $z = 0$ is defined as the laser focusing plane. The contribution of solution species from each illuminated plane to $I_{bulk}$ is a function of the confocal depth (see text).
profile of a focused laser beam in aqueous solution. In principle, all molecules within the illuminated volume of solution contribute to \( N_{\text{bulk}} \). However, the collection efficiency of scattered photons from molecules in each plane of solution varies with confocal depth \( z \), i.e. the distance deviated from the ideal focal plane, where \( z \) equals zero and molecules therein contribute the most to overall intensity, the integrated intensity of which is defined to be \( I_{\text{max}} \). Experimentally, a single crystal silicon wafer immersed in solution can be used to provide the confocal depth profile. The integrated intensity of the strongest band for Si at 520.6 cm\(^{-1}\) was measured as the Si wafer plane was moved up and down vertically, while the confocal position was kept stationary. Figure 3(b) presents the intensity–distance profile that simulated the confocal depth profile. It shows an abrupt decrease in both sides of the ideally focused plane. For the illuminated volume of the solution, a plane of solution can be imaginarily considered to move up and down vertically, just like the realistically moveable Si wafer. It can be seen that the contribution from molecules outside the region of \( |z| > 75 \text{ \mu m} \) is negligible to \( N_{\text{bulk}} \). Now consider an ultra-thin layer of solution with a thickness \( h \) and a volume \( hA \) in the vicinity of the ideally focused plane, in which all the molecules have the same contribution to the overall signal as that in the ideal focal plane. The overall signal can be obtained by integrating the signal on the intensity–depth profile. Thus, the thickness \( h \) can be calculated by Equation (3):

\[
 h = \frac{\int_{-\infty}^{\infty} I(z) \, dz}{I_{\text{max}}} \tag{3}
\]

The \( h \) value (in micrometers) depends on the pinhole size and the objective lens of the Raman microscope. This value can be considered as the key parameter of the confocal characteristic, depending on the pinhole size and the magnification of the objective lens of the Raman instrument. After systematic study on the water overlayer effect on the spatial resolution for the solid–liquid interface we found that the spatial resolution for the confocal system at the same pinhole size and slit width using the same microscopy objective is quite different with and without the water overlayer. The effectively illuminated number of molecules in aqueous solution, \( N_{\text{bulk}} \), can be written as Equation (4):

\[
 N_{\text{bulk}} = AhcN_A \tag{4}
\]

where \( c \) is the concentration of adsorbate, and \( N_A \) is Avogadro’s number. Using Equations (2) and (4), Equation (1) can be rearranged to Equation (5):

\[
 G = \frac{cN_A hI_{\text{surf}}}{RI_{\text{bulk}}} \tag{5}
\]

The value of \( G \) can be obtained after substituting all the known data and constants in the equation.

### 1.3.4 Surface-enhanced Infrared Absorption

Molecules adsorbed on evaporated thin and rough metal films can also exhibit enormously strong IR absorption, which is named SEIRA. Since normal infrared absorption spectroscopy (IRAS) has a sensitivity high enough to detect monolayer adsorbates, and the SEF value is about 50 at the present stage, one might think that the difference in sensitivity is not very important. In fact, only a few groups have been engaged in this field. However, it must be noted that the signal-to-noise ratio of a spectrum is proportional to the square root of the co-added number of interferograms in Fourier transform infrared (FTIR) spectrometry. In IRAS measurements of monolayer adsorbates, hundreds to thousands of interferograms are required to be averaged to enhance the signal-to-noise ratio of the spectrum. In surface-enhanced infrared absorption spectroscopy (SEIRAS) measurements, on the other hand, the same signal-to-noise ratio as IRAS is expected to be obtained without interferogram averaging or with averaging of a smaller number of interferograms, on the basis of simple calculation. Therefore, SEIRAS is suitable not only for obtaining high-quality spectra from submonolayer adsorbate, but also for time-resolved monitoring of reaction processes at surfaces and interfaces.

The IR absorption enhancement has been observed for a variety of molecules and ions adsorbed onto vacuum evaporated thin metal films such as Ag, Au, Cu, In, Pt, Pd, Ni and Al. In general, Ag and Au exhibit the most intense enhancement.\(^{13}\) The enhancement factor changes greatly depending upon the island structure (shapes and size) of the metal film. The enhancement is significant for the chemisorbed first layer and decays as the distance from the surface increases. The distance-dependence was investigated in more detail by using LB monolayers as spacers, and it was shown that the enhancement diminishes about 5 nm from the surface. The enhancement is the largest around the Brewster angle for p-polarization. The enhanced IR bands are superposed on a very broad and strong background absorption by metal island films ranging from the visible to IR regions. The enhanced absorption of the adsorbed molecule is proportional to the background absorption in the mid-IR region. The nature of SEIRA mentioned above is very similar to that of SERS observed on island films, suggesting that the enhancing mechanisms of SEIRA are similar to those of SERS.

The intimate relationship between the enhancement and electric field intensity strongly argues that a certain electromagnetic mechanism is contributing to the

* Traditionally, Raman analysis has been viewed as a relatively insensitive technique. Indeed, the probability of a molecule producing Raman scattering is much less than the probability of absorption in the IR region. However, advances in instrumentation and lasers have narrowed the gap considerably, to the point where, in some optimal cases, the sensitivity of normal (i.e. unenhanced) Raman scatter compares favorably with IR absorption. In addition, the Raman scattering efficiency can be greatly increased by use of surface-enhanced and resonance Raman effects.

* For a single silver nanoparticle or colloid with suitable size, the SEF value can be up 10¹⁴.

* A current limitation is that the IR technique becomes difficult to apply at wavenumbers below about 800 cm⁻¹, because of the low intensity of the thermal IR source in this region. This difficulty can be overcome by the use of a synchrotron radiation source.

* To prepare highly active SERS substrates, proper surface roughening procedures are necessary.

IR enhancement. In the visible region, a short-ranged strong electric field is produced around metal islands via the excitation of localized plasmon or metal islands, which dominantly contributes to the SERS on evaporated metal films. The enhanced local field around the islands is expected to play a role also in SEIRA. Localized plasmon is excited only along the major axis of the ellipsoids in the visible and near-IR regions. Since the major axis is parallel to the substrate surface, the enhancement is observed in the transmission geometry. In the attenuated total reflection (ATR) geometry, the electric field parallel to the substrate surface can give the absorption enhancement. In the external reflection geometry, the substrate is highly reflective; however, no enhancement is observed in the external reflection geometry because the electric field that excites metal islands is polarized normal to the substrate surface. IR absorption can be enhanced through a vibronic coupling of vibrational modes with the charge-transfer between the adsorbed molecule and metal surface. Despite several studies, however, the chemical effect has not been fully elucidated.

Another kind of enhanced IR phenomenon has been reported by Lu et al., who observed the enhancement of the surface IR signal on film surfaces of transition metals (e.g. Pt, Pd and Rh). The observation was made in an external reflection mode. The enhancement factors calculated fall in the range of that for SEIRA, typically 10 to 30. The maximum intensity is related to the film thickness and the metal (~12 nm). The key difference for the so-called abnormal IR effect with SEIRAS is the inversion of the absorption peak of the adsorbate. Although the detailed mechanism of this interesting phenomenon is still unknown, the high sensitivity facilitates the measurement of various surface species (e.g. CO, SCN⁻, CN⁻) on transition metals.

1.4 Surface Infrared and Raman Spectroscopy

Table 1 compares the features of IR and Raman spectroscopy.

2 HISTORY

2.1 History of Surface Infrared Spectroscopy

The use of IR spectroscopy to study adsorbed species dates back to the 1940s. Terenin employed it to investigate
adsorbate on porous glass. Its application to adsorbates on metal surfaces was pioneered in the mid-1950s. The first attempts to obtain spectra from adsorbed layers on bulk metal samples were made in 1959, and in the same year LB films on silver were studied. During the next decade a mass of experimental data appeared and the late 1960s witnessed the expansion of this technique. The theory of reflection at a metal surface, that the optimum angle of incidence is close to grazing, was developed by Greenler in 1966.\(^{(15)}\) Since then, IR spectroscopy has been applied to an ever-increasing range of adsorbates and surface intermediates on many metallic and nonmetallic substrates with the rise of modern surface science, including the study under UHV and of adsorbates on single crystal substrates. In the 1970s the technique came to prominence with much better signal-to-noise ratios and its combination with other modern surface analytical probes. In recent years, the application of Fourier transform techniques has enhanced the performance very significantly, and IRAS is now one of the most sensitive methods of the surface spectroscopic techniques. The limitation of difficulty in the low wavenumber region is now partially solved by the development of synchrotron radiation sources.

IRAS can readily discriminate between adsorbed and gas-phase species and spectra of adsorbed species have been recorded under pressures much higher than atmospheric using the transmission or diffuse reflectance technique with properly designed apparatus. Thus, it is able to bridge the “pressure gap” between surface science and catalytic studies. In the 1990s, sophisticated in situ cells enabled IR study to be carried out in situ over a wide range of temperatures (from liquid nitrogen temperature to 1073 K) and pressures (1 torr to 100 atm).

The application of IR spectroscopy to electrochemistry was first carried out by Bewick et al.\(^{(16)}\) and has undergone an explosive growth. The applications vary from the characterization of adsorbate orientation at submonolayer concentration at electrode surfaces to the determination of short-lived radical ions in the diffusion layer, and from aqueous to nonaqueous solvents. Efforts to improve the sensitivity of these measurements have been made in the late 1980s, and opened the way to probe the reaction dynamics of a variety of heterogeneous and homogeneous chemical processes. Since the 1990s, the emergence of synchrotron sources has promised to yield information regarding interactions between adsorbate and metal substrate, as well as changes in the vibrational modes of species confined within the electrical double layer. Thus various techniques have been proposed to enhance the sensitivity of monolayer adsorbates.

Enhanced IR absorption of organic thin films on Si substrate was reported by Hartstein et al. in 1980 by evaporating Ag or Au thin films onto organic films (metal-overlayer geometry). The enhancement was also observed by forming organic films on very thin metal films evaporated on Si (metal-underlayer geometry). Since the enhancement is rather weak for SEIRA in comparison with SERS, few papers were published in the 1980s. Recently, SEIRA has received renewed interest due to the development of its applications. This interest was triggered by experimental and theoretical studies of the enhancing mechanisms by Osawa,\(^{(13)}\) and by the work of Nishikawa et al. on the application to the trace analysis of chemical compounds.

### 2.2 History of Surface Raman Spectroscopy\(^{(7,8,17,18)}\)

Raman spectroscopy of adsorbed molecules on clean metal surfaces is a relatively new experimental technique in contrast to the related subject of IR spectroscopy of surfaces, which has been actively studied since the pioneering investigations by Terenin (1949) and Eischens (1954). Although cross-sections for Raman scattering are much smaller than those for IR absorption (e.g. \(\sim10^{-29}\text{ cm}^2\) compared to \(\sim10^{-20}\text{ cm}^2\)), Raman spectroscopy enjoys the advantage of quantum detectors and continuous wave (CW) laser excitation of small samples. Burstein et al. studied Raman scattering from a variety of surfaces, beginning with studies of doped InSb crystals in 1968. As early as 1973, Raman spectroscopy excited by red laser has been applied in the study of carriers in p-doped silicon. A review about Raman spectroscopy application in semiconductors and their surfaces presented by Richter appeared in 1976.\(^{(17)}\) In the 1970s, Raman spectra of organic species absorbed on high-area catalysts began to appear but the interest dwindled as fluorescence was found to be a persistent nuisance. Thus in this period, most Raman studies were concerned with the structures of the bulk catalyst itself. The study of adsorbate on the catalyst surface became prominent from the early 1980s. In the mid-1980s near-IR Raman spectroscopy and in the mid-1990s UV Raman spectroscopy were developed, and the renaissance of Raman applications in catalysis began. The first in situ Raman spectroscopic study on an electrochemical system was reported for thin metal oxide and metal halide film electrodes in 1973. Soon after that, the resonance Raman effect was employed to study surface reactions and time-resolved studies on a millisecond scale became possible to detect solution species produced by surface reactions.

The field of SERS was inaugurated in the mid-1970s. The first observation of Raman scattering at a silver electrode surface was made in 1974 by Fleischmann et al. and the full implications of their observations were not clearly recognized. Not until 1977 was it verified that Raman signals arising from pyridine on Ag electrodes were enhanced between four and six orders
of magnitude by Van Duyne et al. and Creighton et al., respectively. Since these first observations, there have been thousands of papers dealing with this phenomenon either theoretically or experimentally.\(^{(8-11,18)}\) Extending SERS to the study of transition metals as well as single crystal surfaces has proved successful in the last 5 years, and single molecule detection by Raman spectroscopy has been accomplished in the past 2 years.\(^{(8,11)}\)

3 INSTRUMENTAL METHODS

3.1 Preparation of Samples

In spite of the fact that IR spectroscopy and Raman spectroscopy can be used to study any solid surface, it is essential to choose the appropriate experimental apparatus, optical geometry, light source and sample preparation for the specific surface studied. In this section, we will discuss various ways of surface sample preparation. Because rough surfaces are more practically important and widely used (the preparation of active surfaces for SERS and SEIRA is vitally important to obtain high quality surface spectra), they will be described and discussed in more detail.

Basically, the solid surface samples can be classified into two categories: the flat surfaces include atomically smooth single crystal surfaces, polished mirror-like surfaces, ultrathin films such as polymer film, LB film and self-assembled monolayers (SAMs) on smooth metallic or nonmetallic substrates; the rough surfaces include micro- or nanoscale rough or porous surfaces, powders and colloids.

Two points may be stressed as to why powders and colloids are discussed at length while the main topic of this article is concerned with the surface: for the films, powders and colloids mentioned in this article, specific attention is paid only to their surface structures, the surface orientations and bonding of adsorbates instead of their bulk structures; the rough, porous and even powder materials discussed here are mainly for significantly increasing the surface area available for adsorption and reaction, and/or generating the SERS and SEIRA activity.

3.1.1 Preparation of the Flat Surfaces

Preparation of the flat surfaces is relatively easy in both IR and Raman measurements. For the mechanical polishing procedure, the solid sample, such as a metal disk sheet or metal rods, is polished first using emery paper followed by polishing with a polishing cloth with wet alumina powder of decreasing size from 5 µm down to 0.05 µm. The flat surfaces undergoing this procedure are either used directly or further treated depending on the experiment. If a well-defined single crystalline surface is being used, either a chemical etching procedure or flame annealing procedure should be used to produce atomically smooth surfaces.

For the ultrathin film samples such as LB films and SAMs, preparation is dependent on the technique. For example, in IR transmission spectroscopy the film is deposited on a transparent substrate such as CaF\(_2\), while in reflectance spectroscopy the film is deposited on a gold film coated substrate. In some cases the flat surface samples are held by adhesion to a spindle capable of rotation about its axis in order to avoid the sample overheating.

In Raman measurements, the laser can be focused on a small area with the aid of a microscope. This means that a very small surface sample, e.g. with diameter of 0.5 mm or less, can be used. However, it may be experimentally difficult if the sample is a very small disk or a thin wire embedded in the holder and its surface needs to be well polished mechanically.

3.1.2 Preparation of the Rough Surfaces

Preparation of the rough surface for surface IR measurement depends on the optical geometry used. In the transmission mode most powder samples are run as potassium bromide disks, as mulls. Although this sampling method provides an easy and adequate way of obtaining spectra, difficulties may arise as a result of water absorption or undesired reactions with the salts. So, some powders and polymer samples are pressed to make a self-supporting film. The thickness is typically between 20 and 1000 µm. In the diffuse reflectance mode samples can be measured as loose powders, with the advantages that not only the tedious preparation of wafers is unnecessary but also that diffusion limitations associated with tightly pressed samples are avoided. It becomes an important advantage in some cases, especially for in situ studying of some catalysis reactions involving diffusion processes. Diffuse reflectance is also the indicated technique for strongly scattering or absorbing particles. ATR or attenuated multiple internal reflectance is also used for the study of dark solids. The sample, prepared as a fine powder, is dispersed on the two faces of a KRS5 (TlBr + TlI) single crystal, which has a high refractive index. Samples for the internal reflectance mode should be dealt with care to ensure that the powders and the surface are in very good contact.

Preparation of the rough surface for ordinary surface Raman (non-SERS) measurements is quite simple. Powders, colloids and rough solid surfaces can all be measured directly in the container in which they are supplied provided that the container is transparent to
the laser and Raman radiation. Powdered catalysts are prepared generally by grinding and calcining. Some powders can be simply held by pressing them into a sample holder, e.g. put on the filter in a capillary tube, or by using a piston to compress them into a soft pellet.

3.1.3 Preparation of Surface-enhanced Raman Scattering-active Substrates(7–11)

It is well known that for obtaining good-quality SERS or SEIRA spectra, the surface must be pretreated properly. Figure 4 illustrates the distinct effect of the surface roughening procedure on the Raman intensity of pyridine adsorbed on Ni electrode surfaces that only have weak SERS activity. The surface signal is extremely weak from the mirror-like surface after mechanical polishing with fine grades of alumina powders down to 0.05 µm. Even the strongest band intensity for the adsorbed pyridine is extremely weak, only about 0.5 counts s⁻¹, Figure 4(a). The spectrum is certainly too weak to be investigated in detail. The signal-to-noise ratio was improved after the electrode was chemically etched in 1.0 mol L⁻¹ solution of HNO₃. The signal intensity increased doubly if the electrode was further treated in a 0.1 mol L⁻¹ solution of KCl by a double-step ORC. An even more intense signal was obtained when the additional ORC was performed in situ in the spectroelectrochemical cell prior to the measurement. These results show that there are several ways to roughen the electrode surface and the correct surface roughening procedure is the key to obtaining reasonably good spectra. As some surface preparations for SERS-active substrates are unique and complicated, they are described in detail in the following.

3.1.3.1 Oxidation–Reduction Cycle

In general the electrode is made of a metal wire, rod or disk sealed into an inert holder (glass, Kel-F or Teflon). The electrode surface is then polished mechanically using decreasing sizes of alumina powders (normally down to 0.3 µm or 0.05 µm). Before the SERS activation procedure

![Graphs in Figure 4](image-url)

The laser excitation line is 632.8 nm.
performed by the electrochemical ORC, the electrode is sometimes treated by a chemical etching procedure for further smoothening the surface and/or by an electrochemical cleaning procedure by controlling the electrode potential to severe hydrogen evolution. Experimental variables in the ORC include the oxidation and reduction potentials, the type of potential–time function utilized (triangular-wave potential sweep or double potential steps), and the amount of charge passed during the oxidation step. The applied potential, especially the oxidation potential, is dictated by the electrolyte and the electrode used. For example, in the case of 0.1 mol L⁻¹ K₂SO₄, oxidation of Ag is accomplished near +0.50 V vs saturated calomel electrode (SCE), the optimum SERS signals are obtained following the charge passage of 20–50 mC cm⁻². This is equivalent to ca. 100–200 monolayers of Ag atoms. For some electrodes such as Pt and Fe, the same SERS signal intensity resulted when the adsorbate was present during the ORC (i.e. in situ ORC) as when the adsorbate was added after the ORC (i.e. ex situ ORC). It has been observed that illumination of some electrodes such as Ag, Cu and Ni during the ORC in the presence of halide can yield a stronger SERS signal. Table 2 is a summary of typical experimental variables for various metal electrodes. Figure 5 shows a roughened Pt electrode and a Au nanorod array that exhibit high SERS activity.

3.1.3.2 Chemical Etching Although chemical etching looks quite simple, it still requires experimental skill to optimize the SERS activity for different metal samples. Copper foils were immersed into 2 mol L⁻¹ HNO₃ solution at 303 K, and after about 10 s bubbles were formed near the copper surface. Vigorous agitation was then applied. After 2 min, a sponge-type surface with substantial roughness was created. In the case of Ag foils, a 5–6 mol L⁻¹ HNO₃ solution was used and the etching time was prolonged to 5–10 min until the surface became milky. For Ni surface, a dilute solution of HNO₃ with concentration about 1 mol L⁻¹ was used, and the etching time was about 5–7 min. For the Fe surface, the best result was obtained by etching in an ultrasonic bath of 2 mol L⁻¹ H₂SO₄ for 5 min. The surface should be gray. After the etching the metal foils or surfaces should be thoroughly rinsed with water and kept wet in order to protect the roughened electrode and to prevent contamination from the atmosphere.

3.1.3.3 Film Deposition Silver and gold form hemispherical particles when thin layers (ca. 5 nm) are vacuum-deposited on various substrates, including silica slides. A new procedure for preparing SERS-active Ag substrate is sputter-depositing Ag onto various substrates (metal, graphite, alumina, and even filter paper). This method produces surfaces that are stable in air and can be SERS-activated by laser irradiation in the presence of an adsorbate that complexes with Ag. Recently, a chemical procedure was developed for preparing silver island films using Tollens’ reagent; this is rapid, simple

</table>
and highly reproducible. Very recently, some rough films of transition metals such as Ru, Rh, Pd, Ni, Co and Fe, exhibiting weak SERS effect, have been prepared by a simple method of electrochemical deposition onto carbon electrode surfaces in the solution containing the metal ions.

3.1.3.4 Chemical Reduction and Laser Ablation

Metal sols are prepared by chemically reducing a dissolved metal salt by means of an appropriate reducing agent in either an aqueous or a nonaqueous medium. Typically, silver sol can be obtained by adding 1 mL \( \frac{2 \times 10^{-3}}{\text{mol L}^{-1}} \text{AgNO}_3 \) into 50 mL \( \frac{5.5 \times 10^{-3}}{\text{mol L}^{-1}} \text{NaBH}_4 \) solution (prepared at 277 K) drop by drop slowly over an ice bath by continuous stirring for 1 h. There is a UV absorption at 380 nm for this kind of sol, and it is yellowish and the solution should be clear. Then the sol is kept in the dark for measurement. It should be noted that the size, shape and aggregation of metal sols could be controlled critically by the solution concentration and composition, mixing rate of the two solutions and the temperature. Metal colloids could also be prepared by exposing metal foil to the focused radiation of high power Nd:YAG (neodymium:yttrium aluminum garnet) laser (55 mJ pulse\(^{-1}\)) pulse for 10 min for silver and gold and 15 min for platinum and copper in 15 mL solvent solution. The solvent could be organic solvent or pure water. Metal colloids prepared by this method are free of interference from the additive.

3.1.3.5 Self-assembled Monolayers Technique

To obtain SERS substrates with ease of preparation, good reproducibility, stability and compatibility with biomolecules, a novel procedure has been developed by Natan et al. based upon the SAMs technique. They arrange monodisperse colloid gold and silver particles regularly onto functionalized metal or glass substrates. Another important aspect of this method is the ability to control the particle size and density, and the space between the substrate and the particle, and thus to tune the electromagnetic characteristics of the surface for systematic study of the SERS mechanism.

3.1.3.6 Lithography

SERS substrate having a very narrow distribution of roughness feature is very important for both fundamental and applied studies. Such SERS substrates have been prepared by nanosphere lithography, in which SERS-active metal is evaporated into preformed arrays of nanospheres which are then removed, leaving behind the metal particles formed in the interstices. An alternative way to obtain regularly structured SERS substrates is to use metal film or particle deposition over periodic arrays of polymer nanospheres or silica posts, which are generated by electron-beam lithography. This allows the optimization of SERS enhancement and investigation of the relationship between the parameters and the enhancement in comparison with conventional island films and also with regularly arranged nanoparticles as mentioned above. The possibility of generating two-dimensional ordered arrays with SERS-active structures with different structural parameters on one substrate in a single production cycle further increases the usefulness of the electron-beam method in the fast development of optimum SERS substrates. By evaporating the metal at a different angle along a direction in which the posts shadow each other, isolated metal particles are obtained on top of each post, with different shape.

3.1.3.7 Overlayer Technique

To extend SERS study to many metals or semiconductors, which only have weak- or non-SERS activity, two important approaches related to the overlayer technique have been made since 1987. The first one is to coat SERS-active Ag or Au electrodes with ultrathin films of metals or semiconductors by electrochemical deposition or evaporation, as developed by Fleischmann et al. and Weaver et al., respectively. With the aid of the long-range effect of the electromagnetic enhancement created by the SERS-active substrate underneath, SERS spectra of adsorbates on these films can be obtained. This method provides
INFRARED AND RAMAN SPECTROSCOPY IN ANALYSIS OF SURFACES

a unique way to study various metal surfaces so as to offer enormous potential for the surface Raman spectroscopic study of catalytically important reactions at surfaces. It can also be extended to study solid–solid interfaces, through which metal oxides, semiconductors, polymer or LB films are coated by different ways onto the SERS-active substrates. Strong SERS signals provide some meaningful information of solid–solid interfacial structures that are difficult to be obtained by other means.

The second is to use the reverse geometry of the overlayer technique, in that the SERS-active metal (e.g. Ag and Au) islands are deposited electrochemically or chemically onto non-SERS-active substrates including semiconductors, metal oxides or polymers, as first carried out by Van Duyne et al. By taking the advantage of the long-range effect of SERS, the structures and properties of the substrates themselves of non-SERS activity can be investigated.

3.1.4 Preparation of Surface-enhanced Infrared Absorption Substrates

Preparation of SEIRA substrates is relatively simple. Very thin metal films are evaporated on IR transparent substrates to form discontinuous layers consisting of small islands. The average dimensions of the islands are about 30 nm in diameter and 10 nm in height for a 10 nm thick Ag film evaporated on a Si substrate. The enhancement factor greatly depends upon the island structure (shapes and size) of the metal film. Slower deposition rate and lower temperature give the larger enhancement.

3.2 Experimental Set-up and Operation Modes

The structure and dynamics of various interfaces, including solid–gas, solid–liquid and solid–solid interfaces, play an increasingly important role in modern science and technology. The ramifications of the subject extend into areas as diverse as catalysis, material corrosion, semiconductor processes, batteries, electric synthesis of organic and inorganic compounds, and biological electron transfer processes. The application of spectroscopy to specific in situ surface (interface) analysis depends on its ability to discriminate between molecules at the surface (interface) and in gas phase, liquid or solid phase. In order to use IR and Raman spectroscopy to study the above systems in situ, it is essential to design the sample cells and apparatus for different chemical and physical environments. In fact, the interfaces can be classified into solid–gas, solid–liquid, solid–solid and solid–UHV interfaces, as discussed below.

3.2.1 Solid–Gas Interfaces

3.2.1.1 Cells

There are many types of IR and Raman cells specially designed for the study of solid–gas interfaces as shown in Figure 6. Here we describe two examples for IR and Raman measurement, respectively, for heterogeneous catalysis with the capability of controlling temperature–pressure–vacuum–atmosphere. These complicated cells can be simplified for the purpose of investigating solid–air and solid–UHV interfaces accordingly. The transmittance IR cells shown in Figure 6(a) and 6(d) are specially designed to treat the sample in situ. The cell is fitted with a furnace, cooling water jackets, gas inlet and outlet, and with BaF$_2$ windows. The cell material should be inert to the catalytic reaction, and can be quartz or stainless steel. The latter cannot be used at high temperature or in some environments where stainless steel can react with the gas. The gas inlet and outlet of the IR cell are connected to two-way and three-way valves, respectively. By switching these valves, the sample in the IR cell can be treated under vacuum exposed to different gas atmospheres or react with a flow of gas mixture. The sample holder of the cell can be heated up to 1073 K. Before the IR experiment, the catalyst was pressed into a self-supported disk then fixed in a slide of ceramic tube that is held in the cell. The sample is first treated in O$_2$ at high temperature, e.g. about 1023 K, for 30 min followed by evacuation under vacuum ($10^{-3}$ torr or lower) at the same temperature until surface contaminants such as carbonate species are completely removed. The treated sample is then cooled down under vacuum to the desired temperature for adsorption or reaction. The reported absorbances were obtained from spectra referenced to the background spectra which were taken.

under vacuum prior to the introduction of the reactants to the catalyst.

The Raman cell for catalysis usually uses backscattering mode because many catalysts are dark in color. Quartz and Pyrex glass are used as the cell materials as they are sufficiently nonreactive to retain many reactive samples like oxidizing agents. For surface Raman measurements, the exciting and scattered frequencies are close to each other and are in the visible range (except for UV Raman measurements). Thus there is generally no problem of cell transparency and quartz is used as the window material. Figure 7 shows a detailed schematic diagram of the Raman cell for Raman microscopy with high performance, including high scattering light throughput, for in situ studies. The Raman cell consists of three parts: sampling, heating (cooling) and sealing. The solid (powder) sample is put on the filter in the capillary parts: sampling, heating (cooling) and sealing. The solid (powder) sample is put on the filter in the capillary tube. The cell is heated by tubular heater, which is placed in a metallic cell, allowing spectra to be obtained under various temperatures, pressures, and gas compositions. Moreover, some cells are designed to be moved up and down using mechanical or pneumatic apparatus for minimizing the thermal effects and damage of the sample by laser beam, see Figure 6(b) and (c).

It is necessary to mention, although very briefly, the cell for ATR or attenuated multiple internal reflectance modes for the study of dark solids. The IR beam enters through the input side of the crystal and reflects from the two faces. The crystal is put into a suitable sample holder, which is placed in a metallic cell, allowing spectra to be obtained at temperatures, pressures, and gas compositions. This method has disadvantages because the crystal may react chemically at temperatures higher than 523 K.

3.2.1.2 Modes\(^{1,19,23}\) Figure 8 illustrates optical geometries for IR spectroscopy, which are the most commonly utilized in surface analysis. They include the transmission, single RA, diffusion reflectance, single internal reflection, (multiple) attenuated total reflectance and emission modes. The techniques are only briefly referred to in this section, since they are covered in detail elsewhere in the Encyclopedia. The emphasis will be laid

(f) Emission mode: the sample is heated and the emitted light is analyzed by the IR detector.
on the experimental set-up for the in situ study of various interfaces.

Transmission Mode. Transmission is the most commonly used IR technique to obtain the spectra of powders. In many circumstances transmission measurements also provide the more direct, robust and reproducible quantitative methods for single-component analyses, operating over a wide dynamic range and at high sensitivity. The powder sample is dispersed in the IR-transparent powder (KBr, CsI, NaCl, etc.) as routine, then is pressed together to form a pellet. However, for in situ investigations on a catalyst this technique is not applicable, and pressed self-supporting wafers have to be used. The applicability of the transmission technique is determined by the properties of the solid powder under study. If the sample is a thin, free-standing film, the transmission technique provides an excellent means of obtaining spectra. One of the disadvantages of transmission IR for supported catalysts is that the spectral range accessible is limited by the transparency of the support. Samples which exhibit only weak bulk absorption, with average particle size \( d \) smaller than the wavelength of the IR radiation in the region of interest, will be optimally suited for the transmission mode. The particle size condition \( (d < \lambda) \) which determines the wavelength range of suitable low scattering losses, is usually met in the mid- and far-IR regions, whereas scattering losses become strongly involved in the near-IR region. However, most samples show strong bulk absorption in the low wavenumber region (roughly \(<800 \text{ cm}^{-1} \)). As a consequence, the low frequency range, in which the vibrational modes of interest for structural characterization of the solid powder material are frequently located, is often not accessible to in situ studies using the pressed-wafer technique in transmission mode. Another drawback of transmission work is that the use of compressed disks limits the diffusion rate of reactants and products, so that kinetic studies are difficult.

Reflectance Modes. The external reflection technique of RA is primarily used for observations on thin films and adsorbates on reflective substrates. Although specular reflectance can be of value as a rapid, nondestructive generic “fingerprinting” tool, and quite extensively used in electrochemistry, its applicability is very limited in solid–gas interfaces. The normal procedure for RA spectroscopy involves the adjustment of the incidence and reflectance angle of the IR beam by about 60–80°. In order to get optimum sensitivity, a grazing angle procedure is used, usually an incidence and reflectance angle of about 80° is employed. The IR beam therefore traverses a considerably longer path through the sample than it does with small angles and produces a stronger spectrum. The diffuse reflectance mode is a convenient means of examining many finely powdered or highly scattering solid samples. It has particular importance for a wide range of near-IR applications. Internal reflection spectroscopy is a technique that measures the optical spectrum of a sample that is in contact with an optically dense and transparent medium. It is most appropriately used to study the surface layer characteristics of a continuous solid sample. This technique was later modified experimentally by increasing the number of reflections, giving rise to attenuated total reflectance spectroscopy, which was originated to study surfaces and thin films. Finally, in specific circumstances, emission spectroscopy provides an alternative and more favorable approach to surface or thin film studies.

Polarization Modulation Techniques. This technique is used to separate surface from bulk-phase absorption in metal–gas interfaces, and the polarization of the incident light is modulated between \( p \)- and \( s \)-polarization in the reflectance mode. In practice, \( s \)-polarized radiation, which has virtually no field strength at the metal surface, is usually filtered since it contains no useful information for adsorbed species. Since only \( p \)-polarized light is surface-sensitive, the modulation between the two polarizations yields an AC signal due to the species at the surface. This results from the fact that the intensity for \( p \)- and \( s \)-polarized light will, on average, be attenuated to the same degree by any randomly oriented gas phase molecules.

In the measurement the detector signal is divided into two channels for signal normalization. One signal proceeds normally, and the interferogram, which is equivalent to the integrated beam intensity in time \( (I_p + I_s)/2 \) is stored. The other signal is demodulated at the photoelastic modulator frequency, giving an interferogram proportional to \( (I_p - I_s)/2 \), which is in turn stored in the instrument computer. These stored interferograms are then Fourier transformed and ratioed to give a normalized intensity \( (I_p - I_s)/(I_p + I_s) \), which is proportional to absorbance. Sum and difference interferograms are alternately sampled during the same interferometer mirror scan.

3.2.1.3 Surface-enhanced Raman Scattering Study on Solid–Gas Interfaces\textsuperscript{(20)} Only a technique with high sensitivity can perform kinetic measurements using real-time measurements, enabling the role of the adsorbed species in the catalytic reaction mechanism to be clarified in situ. Clearly, SERS offers a means to overcome the obstacles of sensitivity, allowing the receipt of surface vibrational data during catalyst reaction. However, SERS has not been applied extensively to study gas–solid interfaces at high gas pressures although it has served as a valuable surface probe in electrochemical environments. Two key stumbling blocks in applying SERS at gas–solid interfaces are often perceived to be the limitation
of metals to be only silver, gold and copper and the lack of thermally stable SERS-active materials of catalytic importance. Based on overlayer strategy (see section 3.1.3.7), SERS study has been readily extended to a range of other materials by depositing them as ultra-thin films on roughened gold substrate. Williams et al.\textsuperscript{(20)} have demonstrated that these electrochemically prepared films also exhibit stable, intense SERS activity in the gas phase over a range of elevated temperatures. The chemical inertness of the gold substrate, especially at elevated temperatures in the gas phase, is a further fortunate circumstance in that SERS signals usually then are associated with adsorption on the catalytic overlayers, rather than on the gold support. SERS can provide in situ information about vibrational modes of adsorbed species over a wide range of gas pressures, without associated problems of bulk-phase interference. Moreover, it allows real-time sequences of Raman spectra for interfacial species to be obtained with a rapidity ($\leq 10$ s) that is commensurate with temperature programmed or other experimental perturbations commonly employed to yield catalytic information.\textsuperscript{(20)}

3.2.2 Solid–Liquid Interfaces\textsuperscript{(16,18,22–24)}

3.2.2.1 Cells Most IR and Raman cells for the in situ study of solid–liquid interfaces at room temperature and ambient pressure are made of glass or Teflon. They are sealed with an optical window with an epoxy resin or with an O-ring seal. The latter method is preferable to eliminate the possible contamination of the electrode and solution from the slow dissolution of the epoxy. Incident radiation passing through the window and solution layer onto the electrode surface is reflected or scattered and is subsequently focused onto the detector. The choice of window material depends on the spectral region of interest and on the solvent. Examples of IR window material for the mid-IR region include calcium fluoride, silicon, and zinc selenide, each of which may be used with a variety of aqueous and nonaqueous electrolytes. For the far-IR region polyethylene is usually employed.

A widely used IR cell and the schematic diagram of the experimental set-up are shown in Figure 9. The working electrode is mounted on a piston constructed either from glass, Teflon or Kel-F. Electrical connection to the working electrode is made through a channel in the plunger. The flat electrode surface is usually polished to a specular finish with an alumina slurry. As a final step, the piston is inserted into the cell and positioned concurrently to ensure that all surfaces are parallel with each other. A Luggin reference probe is positioned about 1 mm from the edge of the working electrode. The counter electrode is typically a platinum wire placed behind the working electrode in a configuration that minimizes solution resistance and provides as symmetric a current distribution pattern to the working electrode as possible.

It is vitally important to avoid strong interference from the same species in the solution phase or solvent by an extremely small quantity of surface (interface) species. This is especially serious for the IR study if the solvent is water, which absorbs strongly throughout most of the mid- and far-IR regions. This problem is minimized by using a thin-layer cell. To obtain the best spectra in IR or non-SERS measurements, one should position the electrode surface about 10 $\mu$m behind the optical window. Further discussion in this aspect will be given in the following sections. It is inferred that SERS has a great advantage in the investigation of two condensed phase interfaces as the thickness of the solution phase can range from 0.5 mm to 5 mm. Therefore, the cell configuration and electrochemical behavior is quite similar to that of the conventional electrochemical cell. For situations where the solution contains strong Raman interference, such as from an organic solvent, a resonance Raman-active species, or a fluorescing species, the working electrode which is parallel to the cell windows in the backscattering configuration can be placed against the windows to greatly reduce the solution pathlength.

Some cells require special design, such as in situ examining of an electrochemical corrosion process at high temperatures and pressures. Melendres\textsuperscript{(22)} designed more complicated cells to study the corrosion and passivation of metals in solution from 298 to 563 K at 100 bar pressure. The design contains all the essential features for this type of work including solution exchange, and could be adapted to suit most instrument arrangements. In Raman spectroscopy, the signal is in proportion to the solid angle of the collecting optics as well as the throughput of the system in use. Pettinger\textsuperscript{(23)} developed

\end{figure}
3.2.2.2 Methods

For studying solid–liquid interfaces, electrochemical instrumentation is generally necessary for the set-up, including a potentiostat and waveform generator (see Figure 9). The latter should be capable of generating a potential pulse and a square triangular waveform superimposed on an initial potential. It should be noted that the thin-layer cell arrangement still exhibits large solvent and electrolyte absorption. There are several methods having signal-to-noise enhancement for surface (interface) species.

**Electrochemically Modulated Infrared Spectroscopy.**

Electrochemically modulated infrared spectroscopy (EMIRS)\(^3\)\(^,\)\(^16\) is the first IR technique applied in electrochemistry that employs electrode potential difference tactics. A change in IR reflectance can result from a change in potential for a number of reasons. These include changes in the coverage of species adsorbed on the electrode, changes in the nature of bonding between adsorbed molecule and the electrode surface, migration of ions into or out of the optical path, and electron-transfer reaction that consume and/or generate species in solution or on the electrode surface. A change in band intensity or the appearance of new bands may result. A band position may change due to changes in the frequency of the oscillator as the strength of bonding to the surface is changed with electrode potential. Since the spectra of the species in bulk solution, electrolyte, solvent and atmosphere generally do not change with potential, they are effectively nulled when two spectra obtained at two potentials respectively are ratioed.

EMIRS measurement is accomplished through the use of phase-sensitive detection and/or signal-averaging techniques. When a dispersive spectrometer is used, the potential is modulated at a frequency dictated by the type of detector used (10 Hz to about 1 kHz). Phase-sensitive detection is used to synchronously demodulate the measured reflectance at a fixed wavelength. Amplification of only that component of the optical signal having the same frequency as the modulation and appropriately related in-phase with the potential modulation increases the sensitivity to the level adequate for detection of IR bands of submonolayer quantities of adsorbates. The wavelength is incrementally scanned over the desired spectral region and the signal integrated at each wavelength. Signal averaging of several spectra further enhances the signal-to-noise ratio. The difference in the IR reflectivities normalized to the absolute reflectivity, \(\Delta R/R\), as a function of wavelength effectively removes the wavenumber dependence of instrumental energy throughput, detector sensitivity, and electronic response throughout the beam path. It yields the difference in the IR spectra between the two electrode potentials. Figure 10 illustrates some possible difference spectra, by which different vibrational characteristics on potential changing can be deduced. EMIRS offers great sensitivity under favorable conditions, with \(\Delta R/R\) values as small as \(10^{-9}\) being detectable.

**Electrochemical Infrared Absorbance Spectroscopy.**

Electrochemical infrared absorbance spectroscopy (EC-IRAS)\(^3\) is now the most commonly used IR technique in electrochemistry, that also involves the acquisition of \(\Delta R/R\) values, usually between two electrode potentials, but now by acquiring a suitable number of interferograms at fixed potential between each modulation, then

![Figure 10](image-url)
co-adding those obtained at $E_1$ and $E_2$. The multiplex advantage of the Fourier transform technique allows for very rapid spectral acquisition, but there is lower noise discrimination per scan than in EMIRS. The time to obtain spectra by each technique at the same sensitivity is therefore approximately the same. Consequently, the rate of potential modulation is considerably less than in EMIRS, typically $10^{-3}$–0.1 Hz. A schematic diagram for this technique is shown in Figure 9, from which one can deduce many potential dependent characteristics of surface species. This method was originally dubbed ‘subtractively normalized interfacial Fourier transform infrared spectroscopy’ (SNIFTIRS). As this method is now so commonly used in electrochemistry, many people refer to it as EC-IRAS for simplicity. To stress the employment of potential-difference tactics in electrochemistry, some groups also refer to it as potential difference infrared spectroscopy (PDIRS).

EC-IRAS offers considerably greater flexibility in the electrode potential waveform that can be employed, broadening the applicability of the method to encompass reactive as well as stable electrochemical systems. Data accumulation may be accomplished by various means. For example, sequences of potential-difference spectra can be obtained during a single electrode potential-step or -sweep waveform, enabling irreversible voltammetric conversions of adsorbed species to be monitored in a fashion that is not feasible with EMIRS. The simple potential-step method has several advantages. One is that electronic and mechanical drifts over long periods of time are cancelled effectively. Also, interference from atmospheric absorbances due to water and carbon dioxide may be easily eliminated by cancellation in the ratioing of the spectra. Next, since substantial product accumulation may occur in some electrochemical systems over long time periods, the measured difference signal could be decreased if the potential is held at a fixed value for a long period of time.

Polarization Modulation Techniques. As has been mentioned for the solid–gas interface systems, the polarization of the incident light can be modulated between p- and s-polarization so the measurement can be performed without an alteration of the applied potential in electrochemical systems. Polarization modulation at a fixed electrode potential is an important technique in that it differentiates between adsorbed and dissolved species, but the sensitivity is relatively low. Moreover, this separation of surface and bulk phase is usually incomplete since the p/s interfacial demarcation extends the order of a wavelength from the metal surface. A distance comparable to the thickness of the electrochemical thin layers (ca. $10^{-3}$ mm) usually is employed. It may be noted that some authors use the acronym IRAS to denote specifically the p/s modulation technique.

Methods for Surface Raman Measurement. Three methods have been used for surface Raman spectroscopic studies, the 90° geometry, the backscattering geometry and the ATR configuration. In the first geometry, a focusing lens is used to focus the laser beam at a spot on the surface, the incident light making an angle of 90° with the optic axis of the monochromator. In this configuration, the electrochemical cell must have an optically flat cell bottom through which the excitation light enters and an optically flat side through which the scattered light exits. In the backscattering geometry, only one side of the electrochemical cell must have an optically flat window. In the configuration, the focusing lens may be a cylindrical lens which produces a line image for fitting the slits of the Raman spectrometer. An angle of incidence of around 45° can be used between the incident laser light and the optic axis of the monochromator. This geometry has some advantages over the 90° geometry when the reflected light does not come near the entrance slit of the monochromator.

Attenuated Total Reflection Configuration for Raman Measurement. SERS of adsorbates at a metal surface is mostly restricted to roughened surfaces showing a larger surface enhancement. The application of the ATR method in Raman spectroscopy provides a novel and essential way to study mirror-like polished metals, in particular single crystalline surfaces without additional mild-roughening procedure. The ATR method is used to excite surface plasmon polaritons (SPPs) at the smooth metal surface to improve the sensitivity in Raman spectroscopy by electromagnetic field enhancement. The enhancement of the ATR configuration with respect to the normal external reflection geometry ranges from one to three orders, depending on the electrodes and their crystallographic orientations.

Figure 11 shows the ATR configuration under electrochemical working condition. The Weierstrass prism made of ZnSe (radius $r = 5$ mm, refractive index $n = 2.6$ at $647$ nm excitation) which is longer by $r/n$ than a hemispherical prism is mounted in the bottom of the electrochemical cell. The experimental procedure is much more difficult than that of normal SERS measurement. The single crystal electrode is carefully pressed against the prism with a micrometer and a spring, so that the optimum gap size $d$ for the SPP excitation (about half a wavelength) can be adjusted. By moving the p-polarized laser beam with a small prism perpendicular to the optical axis, the angle of incidence $\alpha$ with respect to the surface normal and therefore the momentum of the incident photon can be controlled. The laser beam is reflected at
the prism base and the intensity of the reflected beam can be measured by a photo diode. When the angle of incidence and the gap size are close to the optimum conditions for SPP excitation, a bright cone of scattered light is emitted and appears as a sharp ring behind the 1:1 collection objective. The intensity of the reflected light goes to zero and the Raman intensity has a maximum under optimum conditions, so that a fine adjustment of the experimental parameters is possible. For example, the optimum condition for SPP excitation at $\lambda = 647$ nm was found to be at $\alpha = 34^\circ$. The scattered light is collected by an additional objective which provides a good matching to the monochromator. With the extra enhancement given by the ATR method, it was possible to study the Raman signal of adsorbates at electropolished single crystal electrodes, including Ag, Cu, Pt and Ni as a function of the electrochemical potential.

With the polarization analyzer in place, polarization studies can be made by measuring the scattered light with the analyzer oriented so that only light with its electric vector parallel to the scattering plane is passed. Then the measurement is made with the analyzer rotated exactly 90° so that only plane-polarized light with the electric vector perpendicular to the scattering plane is passed. The scattering plane can be defined as the plane made by the direction of propagation of the incident laser light. In any optical configuration, the angle of incidence can be varied by rotating the electrode orientation with the micropositioner. To facilitate alignment, the cell can be mounted on an $x$-$y$-$z$ micropositioner which has provisions for translations as well as rotation in the vertical plane that the optic axis of the monochromator makes with the entrance slit.

To improve the detection sensitivity, the main consideration for the collection lens is that it should have as low an $f$ number as feasible in order to collect as much scattered light as possible. Also the ratio of the collection lens radius to the distance between the lens and the entrance slit should be equal to the ratio of the radius of the first optical element in the monochromator to its distance to the entrance slit. This condition will ensure that the scattered light will fill the spectrometer optics, giving optimum sensitivity and resolving power.

3.2.3 Solid–Solid Interfaces

Monolayers and multilayer (or polymer) films are ubiquitous in nature, forming at the interface between two phases and affecting the surface properties in a variety of ways. They may be present as a reaction front between two materials, as in corrosion or rusting of metals, or they can be specifically formed to prevent such corrosion from occurring. An understanding of the role of the physical chemistry of the film–metal and polymer–metal interfaces is critical to the control of the final properties of the composites. Molecular level characterization of the solid–solid interfaces by IR and Raman spectroscopy is therefore highly desirable. The IR and Raman study on solid–solid interfaces is much less extensive in comparison with that on the solid–gas and solid–liquid interfaces. As a consequence, the cell and method employed are relatively simple, and will not be described here in detail. However, it should be noted that for probing solid–solid interfaces, at least one solid phase must be thin enough to be transparent to the light beam.

IR spectroscopy is an ideal probe of the structure and orientation in deposited films because of its sensitivity to chemical and physical properties. Recent examples in the literature are extremely diverse. When LB and SAM films are deposited upon metal surfaces, the effect of the metal surface selection rule upon various bands in IR RA spectra can be used to determine the average orientation with respect to the surface normal. In fact, the calculation of chain alignment with respect to a surface
is also of interest to protein and polymer science and a number of computational techniques used in these areas may be of relevance to surface thin-film structure. Most of these studies were carried out in an ATR configuration in order to provide sufficiently high sensitivity.

Raman study of film–metal and polymer–metal interfaces usually involves a certain kind of enhancement to prevent strong interference by the solid phase. Signal enhancement can usually be achieved by depositing films onto the surfaces of noble metals such as Ag and Au, to make use of the SERS effect. For materials with electronic transitions in the visible, the resonance Raman effect can be utilized to enhance certain bands. Furthermore, surface-enhanced resonance Raman spectroscopy of various dye layers has been reported, and the polarized Raman scattering has been proved to be useful in determining the orientation of the molecular orientation of the molecules in films. However, direct measurements of the interfacial structure have long been a difficulty. Polymers adsorbed from a solution usually form multilayers on a solid surface. A “very thin layer” of polymer formed on a metal is usually at least tens or hundreds of angstroms thick. Thus, the film of polymer on metal must be a few hundreds of angstroms thick in order to cover the surface entirely while the interfacial region relates only to a few or a few tens of angstroms of polymer adjacent to the metal surface. It is therefore difficult to measure the interfacial region without the interference of the polymer bulk. SERS is ideal for the study of polymer–metal interfaces since it enhances almost exclusively the first monolayer of molecules adjacent to the surface. That makes it possible to examine the interfacial region between metal and polymer as long as the polymer films are not so thick that normal Raman scattering is stronger than that from the interface. Another advantage of SERS for polymer studies is its fluorescence-quenching property. Normal Raman spectra cannot be obtained from many samples because of the curtain of fluorescence that hides them. In the visible excitation region, most polymers are not amenable to Raman analysis because of fluorescence. Adsorption of molecules on the SERS-active metal surface causes fluorescence quenching in highly fluorescent compounds. Fourier transform Raman spectroscopy is considered as a proper technique for studying such specific interfaces.

3.2.4 Solid–Ultra High Vacuum Interfaces

In spite of the fact that increasing emphasis in recent years has been placed on in situ vibrational spectroscopy in studying various interfaces under working conditions, as has been stated above, ex situ methods of surface characterization under UHV conditions are still of substantial fundamental and practical value. As can be seen in this Encyclopedia, the highly sensitive UHV-based EELS technique can yield detailed surface vibrational data as an ex situ method. Similar remarks also apply to surface IR and surface Raman spectroscopy, although these techniques have been used even more rarely in this way.

Ex situ IR and Raman spectroscopies are considered as complementary techniques to EELS, particularly for studying some complex interfaces. Taking the investigation on an electrochemical interface as an example, a general limitation of the ex situ method is that the ambient-temperature transfer into UHV usually removes solvent and other volatile interfacial components, so that the double-layer structure will be significantly or even drastically altered. An alternative UHV-based approach, pioneered by Sass in 1988, entails forming electrochemically relevant interfaces by sequential gas-phase dosing onto a clean metal surface of some or all of the various components (solvent, solute, electrolyte ions, etc.) which collectively form a double layer. This strategy is often known as “UHV double-layer modeling”. It can yield unique insight into the nature of double-layer interactions, and also provides an integrated stepwise link between the multi-component electrochemical interfaces and constituent metal–UHV systems. An additional but important advantage of this approach is to overcome the problem of strong interference due to the bulk solution phase for surface IR spectroscopy. It should be noted that low temperatures (typically <150 K) are required at the solid–UHV interfaces to prevent evaporation of volatile components, such an interfacial structure involving water as the solvent is very different from that of solid–electrolyte interfaces. However, the fundamental nature of ion–solvent and other interactions should be insensitive to temperature. This unique approach has the obvious virtue of enabling UHV-based techniques such as EELS to be exploited and combined with IR and Raman techniques for interfacial characterization. Vibrational data obtained along these lines are considered as a link between the structural properties of in situ electrochemistry or catalysis and metal–UHV interfaces. Weaver and Zou have carried out systematic work on this important approach, and have published a review recently.

3.3 Newly Developing Methods

In the 1990s, especially in the last 5 years, several important techniques of surface IR and Raman spectroscopy have been developing very rapidly, including IR and Raman microscopies, time-resolved IR and Raman spectroscopies, UV-resonance Raman spectroscopy, and scanning near-field optical microscopy (SNOM). These techniques have distinct advantages individually either in high detection sensitivity, or high spatial-resolution, or...
high time-resolution. Combination of these techniques to maximize the advantages will certainly make them increasingly important and become key tools in surface analysis in the 21st century. Therefore, we include these newly developing techniques in this section.

3.3.1 Single Molecule Spectroscopy\(^{29,30}\)

Single molecule imaging and spectroscopy is of basic scientific and practical interest and has been the subject of considerable effort over the past few years. SERS is a phenomenon resulting in strongly increased Raman signals of molecules that have been attached to nanometer-sized metallic structure. The enormous surface enhancement must be utilized to make single molecule Raman spectroscopy a reality. Recently, two groups have achieved this goal using different approaches. Kneipp et al.\(^{29}\) detected successfully a single molecule of crystal violet adsorbed on aggregated silver colloids. They used near-IR excitation which is not resonant with any intramolecular optical transitions of the dye but efficiently excites the plasmons of the aggregated colloids. On the other hand, Nie and Emory\(^{30}\) combined SERS effect and normal resonance effect to produce the required sensitivity to detect a dye molecule adsorbed on the surface of a single silver particle.

Nie et al. used standard citrate reduction techniques to produce silver sols which comprised a heterogeneous collection of mostly unaggregated particles of various sizes and shapes. Surprisingly, a small number of these particles showed extraordinarily high enhancements, that are labeled “hot” particles. These special particles can be imaged by bandpass filtering the Raman scattering of adsorbed Rhodamine 6G. Combined optical and atomic force microscopy (AFM) measurements showed that most of these particles were isolated with dimensions of ca. 80–100 nm and have shapes which ranged from spherical to rod-like. This result is in general agreement with the electromagnetic theory of SERS that the surface plasmon resonance frequency is a function of particle size. However, the large enhancement factors observed cannot be accounted for solely by electromagnetic theory.\(^{7,9}\)

Figure 12 shows some particularly interesting spectra. It indicates that much more intense scattering was observed when the laser polarization was aligned along the long axis of an ellipsoidal particle which is the most polarizable direction. This result is in contrast to what is commonly recognized – that SERS is depolarized. Further, in a series of Raman spectra taken from a single molecule at different times, fluctuations both in frequency and intensity were observed. These results clearly illustrate the high potential of SERS among single molecule detection methods, not only for its tremendously high sensitivity, but also its capability to characterize the molecular structure, orientation and dynamics.

3.3.2 Infrared and Raman Microscopy and Spatially Resolved Measurements\(^{31,32}\)

IR microscopy and Raman microscopy are hybrids of optical microscopy and IR spectroscopy or Raman spectroscopy and, as a consequence, have all the concomitant advantages of both techniques. The surface signal is analyzed by an optical microscope coupled to the IR spectrometer or Raman spectrometer. The vibrational frequency shift is analyzed at different points of the surface. IR microscopy and Raman microscopy can resolve parts with different chemical composition in a surface and are sometimes referred to as chemical imaging. They have been applied to the study of inhomogeneous surfaces, thin films, coatings, microelectronic integrated circuits, biological tissues, and others. Their advantages and some technical details related to surface analysis are discussed.

3.3.2.1 Infrared and Raman Microscopy

For increasing the spatial resolution and detection sensitivity in surface analysis, two important characteristics of a microscope lens are its magnification and its NA. Magnification is simply the ratio of the image size to the object size. NA is given by $\text{NA} = n \sin \theta$. The magnification is important only to the visual operation of the microscope, since it does not affect energy throughput. However, the NA is directly proportional to the energy throughput and so should be as high as practical. Typical NAs of IR microscopic lenses are 0.5–0.7. In IR microscopy the source of radiation is the normal source of the IR spectrometer, namely a heated body, often just a nichrome resistance wire. All IR microscopes use Cassegrains as objective lenses, but there is variation between microscopes as to whether off-axis or on-axis elements are used for other purposes. The reflection mode is feasible with the microscope by the utilization of specialized accessories. A grazing angle objective and an ATR objective that utilizes various high-density hemispheres (ZnS, KRS-5, germanium, diamond, etc.) are also commercially available and simply replace the normal Cassegrain lens in the microscope for such studies, which could be valuable for analyzing some surfaces.

For a Raman microscope, the main purposes of the microscope are to excite and collect Raman radiation very efficiently from the sample and to provide a means for sample positioning and viewing at high magnification. Raman scattered radiation is collected 180° to the incident excitation by the same objective and transmitted back through the beam splitter. In most Raman microscopes holographic notch filters are employed as the beam splitter of the microscope, and the means by which Rayleigh rejection is achieved. This achievement allows the use of a single short focal length monochromator (0.25 m). However, for extremely low wavenumber
shift information (i.e. 2 to 20 cm\(^{-1}\) shift), a double monochromator may be required. Additional gains have been achieved by employing the notch filter as a beam splitter. The filter reflects the excitation wavelength with an efficiency of better than 90\% and transmits the Raman scattered radiation with a similar efficiency. No compromise is made between excitation and collection of the Raman scattered light. The overall benefit is that the size and cost of Raman microprobes have been reduced considerably and the surface sensitivity increased remarkably. The latter is extremely important to surface (interface) studies. The intensity of Raman scattering is proportional to the irradiance (power/area of cross-section) of the exciting beam. The Raman intensity depends critically on the solid angle \(\Omega\) over which the scattered light is collected.

3.3.2.2 Raman and Infrared Imaging Techniques\(^{(33)}\)

There are two types of sampling technique in Raman and IR imaging, global imaging and point-by-point mapping. One unique feature of the Raman or IR microscope is the ability to obtain a microscopic image of a sample through the use of discrete wavelength segments of the spectrum of Raman or IR signal originating from a light-irradiated sample. The system utilizes the multiplex advantage of a two-dimensional low light level television-type electronic camera detector. The principle involved is that the sample is placed under the microscope and the light beam illuminates the whole field of view of the microscope. From Raman imaging, this was achieved by rotating the laser beam to form an annular beam of light which is directed to the condenser of a dark-field microscope objective. Thus the sample is uniformly irradiated with monochromatic radiation. The microscope then transfers the image of the sample to a monochromator which selects the desired wavelength to be imaged onto a television camera placed at the exit focal plane. If the wavelength selected corresponds to a Raman band frequency of a component of the
surface, the micrographic image indicates the distribution of the component throughout the illuminated area. The spatial resolution of the system is about 1 μm. This system works well for surfaces which are good Raman scatterers but tends not to work with poor Raman scatterers and could not easily discriminate Raman features from fluorescent backgrounds. The big advantage of this method of Raman imaging is that the detector observes the entire field simultaneously.

Another approach is to use a computer-controlled stepping motor driven sample stage on the microscope relative to the stationary focused laser beam. In this procedure the spectra are detected at several hundred positions on a sample surface. A computer is programmed to record a set of spectra point by point. This procedure is repeated until all of the necessary data are recorded and stored from the area studied. In this way either one-dimensional mapping line profiles or two-dimensional maps of the species present on the surface are built up.

A different approach is to scan the focused laser beam over the stationary sample and record the spectrum at different locations on the surface. This method is achieved by a new kind of transfer optics placed between the microscope and the spectrometer, which enables an optimized coupling. The coupling optics consists of a pair of lenses. One lens, optically coupled to the back aperture of the objective can be moved in two orthogonal directions perpendicular to the laser beam. Thus this lens can focus the light beam on any point in the microscope field and therefore on any point of the sample. The second lens is mechanically coupled to the first and placed in the scattered beam to balance any shift in the image probed area and focus the scattered beam on the entrance slit of the spectrometer. The optical arrangement has proved to be convenient for a variety of cumbersome surface samples, such as variable temperature or pressure cells.

3.3.3 Time-resolved Spectroscopic Measurements

IR and Raman spectroscopy are in principle amenable to the dynamic study. The conceptually most straightforward extensions into this field are time-resolved investigations. Here, changes in molecular structure and interaction at the surface initiated by some external action at a given time are monitored. This is surely an important advantage over other vibrational spectroscopies including EELS and neutron scattering techniques. During the last 15 years several technical developments in the light source and detector made time-resolved IR spectroscopy and Raman spectroscopy an important branch of time-resolved surface spectroscopy. It should be emphasized that there are two kinds of time-resolved studies: (i) the measurement is triggered by a certain surface process (reaction). By applying a potential pulse to the electrode or injecting reactive gas to the catalyst, one can monitor the whole dynamic process from the catalyst, one can monitor the whole dynamic process from both spectral and temporal aspects; (ii) the measurement is performed at steady state of the surface process that can be disturbed by a pump light beam and probed by another light beam. The first method is relatively simple, but has attracted more attention as it can obtain a lot of information, such as the reaction intermediate and pathway as well as reconstruction (or phase transition) of the surface adlayer. The second method requires expensive pulse lasers, and is suitable to probe surface charge transfer processes and characterize vibrational energy transfer rates for surface species.

3.3.3.1 Time-resolved Infrared Study

As in all kinds of time-resolved spectroscopy, the principal quantity to be measured is the spectral and temporal dependence of the radiation intensity (here IR radiation). Femtosecond-to millisecond-scale time-resolved surface IR studies have been achieved. They involve the investigation of energy transfer at the surface (femtosecond),

\[ 34 \]

the photochemical process (picosecond), the structure and dynamics of the excited states (nanosecond), structural change during temperature, pressure or electric stimulation (microsecond), and the chemical or electrochemical reaction (microsecond to millisecond even down to seconds). The instrumentation is totally different to provide a time resolution higher or lower than 1 ns.

When the time-resolution is higher than 1 ns, because of the very fast signals involved, it is no longer possible to record electronically the complete time course of the intensity change. Instead, the so-called pump-probe technique is employed. The essence of this technique is that the system is perturbed from equilibrium by a very short laser pulse. The system’s response to the perturbation as well as the decay back to equilibrium are monitored by a second, time-delayed laser pulse. By repeating the experiments with different delays, the time course of the intensity change of the monitoring pulse caused by the exciting pulse is obtained. Evidently, this scheme allows for the direct observation of the dynamic behavior of the system. To obtain a precise time correlation between the exciting and monitoring pulses, both are derived from the same master laser pulse. IR pulses are generated by nonlinear methods from visible pulses with a pulse-width well below 1 ps using present laser technology. In vibrational spectroscopy, which usually requires a considerably higher spectral resolution than UV/visible spectroscopy, one has to take into account the time-energy uncertainty principle. A transform-limited pulse with a duration of 0.1 ps exhibits a spectral bandwidth of about 27 cm\(^{-1}\).

It should be noted that most nanoscale or picoscale analyses have been carried out at static condition.
(e.g. potential, temperature or pressure) after ultrafast perturbation. To bridge the kinetic and structural analyses and to obtain a deeper insight into the dynamic processes occurring in the interface, time-resolved surface analyses are required to be carried out at the same timescale (microseconds to milliseconds), i.e. coupled with the surface dynamic process.\textsuperscript{(35,36)} There are two kinds of technique to perform time-resolved IR study with time resolution lower than nanoscale, the continuous-scan technique and the step-scan technique. The IR intensity changes caused by the external distortion can now be measured with a fast detector and the corresponding signal-acquisition electronics. The continuous scan has a varying time resolution from nanoseconds to tens of milliseconds in different sources (tunable laser or broad-band IR source), and acquisition mode (rapid scan and stroboscopic) with different triggering methods (zero-crossings of the helium–neon laser interferogram, asynchronous or fast digitalization triggering).

The step-scan technique is a newly developed technique very useful for time-resolved studies. The step-by-step optical retardation change is achieved by a combination of a constant motion of the moving mirror and a sawtooth-like motion of the fixed mirror for the FTIR spectrometer. The minimum time resolution is limited by the analog-to-digital converter which is about 5\,µs. Step scan time-resolved spectroscopy can be used to collect spectral and kinetic information on repeatable processes that are typically initiated by electronic pulse, laser pulse, temperature jump or rapid mixing.

Although time-resolved IR spectroscopy provides dynamic and kinetic information on surface sorption and reactions, the interpretation of the spectra is not easy if IR bands of reactants, intermediates and final products are highly overlapping. The two-dimensional IR technique could be used to differentiate overlapping bands and to highlight dynamic and kinetic information involved in the time-resolved spectra. In two-dimensional IR, a spectrum defined by two independent wavenumbers is generated by a cross-correlation analysis of dynamic fluctuations of IR signals induced by a sample perturbation (e.g. potential modulation). The cross-correlation analysis includes synchronous and asynchronous correlations which characterize the coherence of dynamic and the independent fluctuations of IR signals, respectively. The sign of the synchronous correlations indicates the relative direction of change in dynamic spectral response, while the asynchronous correlation provides the temporal relationship between the intensity fluctuations at different wavenumbers.\textsuperscript{(13)}

3.3.3.2 Time-resolved Raman Studies
Raman spectroscopy can also provide quite high time resolution, which affords additional information about various surface (interface) processes. However, due to the intrinsic low sensitivity it provides, conventional surface Raman spectroscopy is not considered suitable for time-resolved investigations for timescales shorter than several tens of seconds. With the application of SERS effect or resonance Raman effect, high time resolution reaching the picosecond scale with reasonable signal-to-noise ratio has been obtained.

The detailed operation of time-resolved Raman measurement depends on what kind of study is being performed. It can be divided into three categories: (i) using a CW laser, time resolution depends on the detector; (ii) using a pulse laser, the time resolution depends on the pulse width of the laser; (iii) combining with electrochemical transient technique, the time resolution depends neither on the detector nor the laser but on the electrochemical set-up (see section 3.3.3.3).

For those using CW laser, several kinds of detectors have been employed. For the tunable monochromatic technique a single channel detection system, such as a photon multiplier tube, is used. The time-resolved Raman investigation can only be done with the grating set at the desired peak position (frequency). The spectral band of the surface species is in general quite broad and the entrance and exit slits are tuned at a wider width for detecting the signal of whole band. The signal is collected after the external signal pulse in a standstill mode (also called the intensity–time curve). Provided there is sufficient signal intensity, the time-resolved value depends on the response rate of the detector.

For the multichannel detection system normally two kinds of detectors are used; the intensified charge coupled device (ICCD) detector and the intensified photodiode array (PDA), which have a very fast response rate. Without a gating system, the best time resolution provided is only about tens of milliseconds. In this case, the external perturbation (external temperature, pressure, or electrode potential change) is applied to the sample, triggering the Raman spectra to be recorded successively, giving a series of time-dependent spectra.\textsuperscript{(37)} With the use of the gating system, as low as 1 ps is possible. However, in order to synchronize the process studied and the detection system, the pump and probe technique has to be employed to acquire the signal of the process occurring at a fixed potential after perturbation by a light or magnetic field. The time resolution value is determined by the signal and the response rate of the detector. The higher the time resolution value anticipated, the stronger the Raman signal should be. Thus, in the nanosecond resolved Raman study, a molecule with very strong resonance and/or surface enhanced Raman effect is adopted in order to provide a strong enough signal. For example, Shi et al.\textsuperscript{(38)}
ally, the application of Raman spectroscopy to catalyst characterization has been limited (i) by the small Raman scattering cross-sections typical for excitation at the visible wavelengths available from commercial, CW lasers and (ii) by interference from sample fluorescence and luminescence, which often produce a huge background compared with the weak Raman bands. Typical catalyst surfaces are often covered by carbonaceous residues (coke) during reaction or deposition. These samples often exhibit strong fluorescence, which makes detection of the weak Raman signals impossible. Therefore, both an increase in the intensity of Raman signals and a decrease in the intensity of background fluorescence would make a substantial advancement in the application of Raman spectroscopy to practical material characterization. This has recently been achieved by the application of UV resonance Raman spectroscopy. Using UV excitation, the variety of samples where useful Raman spectra can be obtained has been dramatically increased. For example, good-quality Raman spectra that are nearly free of fluorescence interference have been obtained from deeply colored, heavily coked catalysts and chemical vapor deposited diamond film. Moreover, since the Raman scattering cross-section is generally larger using UV excitation compared to visible or near-IR excitation, the sensitivity of UV Raman spectroscopy is correspondingly greater. In addition, the intensity of Raman bands can be greatly enhanced owing to the resonance Raman effect when the excitation line is accessible to the electronic absorption of the surface or surface species. As a consequence, it is possible to obtain spectra of supported oxide catalysts at loadings below the detection limit of conventional Raman spectroscopy.

3.3.5 Surface-enhanced Resonance Raman Spectroscopy

At present, this technique seems not to be so promising as those mentioned above. However, along with the rapid development in laser technology, wavelength tunable lasers ranging from near-IR to UV will be adopted in most laboratories in future so that surface resonance Raman spectroscopy together with surface-enhanced resonance Raman spectroscopy will be probably developed into a powerful tool. A molecule adsorbed at a surface or within the diffusion layer, when excited by light within its absorption band, has enough scattering intensity even at very low concentration to give a resonance Raman spectrum. This type of spectrum will be potential dependent if the Raman resonance-active species is generated by the surface process (reaction). With the resonance Raman effect, a resonance Raman spectrum of good quality can be obtained on smooth non-SERS-active substrates, even atomically smooth single crystal surfaces.
If the resonance Raman scattering can also be enhanced by a SERS-active metal concurrently, i.e. by a surface-enhanced resonance Raman scattering (SERRS) process, SERRS spectroscopy has extremely high sensitivity with an enhancement factor larger than \(10^{10}\). It should be stressed that due to the participation of the metal, for the molecules near the surface, the resonance Raman process is damped by energy transfer to the metal, with a more severe damping of the fluorescence at the surface. It is possible to obtain SERRS in the absence of an interfering fluorescence background. The combination of advantages of SERS and SERRS effect will make this technique one of the most sensitive methods in surface science, which could be valuable for trace analysis and even for single molecular detection.\(^{(30)}\)

### 3.4 Troubleshooting

#### 3.4.1 Detection Sensitivity

As the number of surface species under study is usually extremely small, ten times less than a monolayer (a few tenths of a nanomole in quantity), the most serious problem, especially for studying the interface of two condensed phases, is the detection sensitivity. Thus it is vitally important to optimize the experimental set-up from every aspect. It has been found that most trouble is caused by optical alignment related to the cell and sample.

#### 3.4.1.1 Raman Measurements of Solid–Liquid Interfaces

For a microprobe Raman system, the solution layer of the electrochemical system could affect dramatically the collection efficiency of the microscope and the optical alignment. An investigation on the effect of the thickness of the solution layer on the Raman signal detected revealed that decreasing the solution layer thickness from about 2 mm, 1 mm, 0.5 mm to 0.2 mm, the Raman intensity increases 35%, 52%, 71% and 89% of the maximum intensity obtained on a silicon wafer without a water overlayer. At a thickness of 0.2 mm, the Raman intensity suffers only about 10% loss and the solution layer with this thickness will not affect the electrochemical process much. This thickness was used as the optimized condition after considering both the Raman intensity and the electrochemical processes. Furthermore, in the electrochemical system, most electrolytes are corrosive, so to protect the objective a cover glass or quartz window has to be employed between the electrolyte and objective; this results in 50% loss of the signal. An alternative way to protect the objective is to wrap the objective a very thin poly(vinyl chloride) film (benefit from confocal set-up: no signal from poly(vinyl chloride) could be detected in this configuration). Using this approach, the Raman signal only suffers a 20% loss. The disadvantage of this approach is that without the quartz window, the solution has to be exposed to the air, and impurities in air will contaminate the solution studied. For a system very sensitive to impurities, the thin quartz window has to be employed at the cost of intensity.

The water overlayer in an electrochemical system greatly affects the vertical spatial resolution of the confocal system. For example, with smaller pinhole size (300 µm), the spatial resolution is about 17 µm and 19 µm without and with solution layer, while when the size is about 600 µm, the spatial resolution amounts to 21 and 53 µm for the surface without and with solution layer, respectively. This indicates that in an experiment high spatial resolution is desired, decreasing the pinhole size is a very effective way to eliminate the distortion of the solution layer to the optical path.

#### 3.4.1.2 Electrochemical Infrared Absorption Spectroscopy Measurements

In EC-IRAS experiments, crucial to the success of this technique is the formation of a thin solution layer between the IR window and the surface by pressing the electrode against the window carefully and firmly. This approach reduces the background absorption due to the bulk solution which is very large in the case of aqueous solutions. To position the electrode surface exactly parallel to the window, it is better to use a spring as a “soft” connection of the electrode to the holder so that the optimum position can be adjusted. It should be also pointed out that the higher the reflectivity of the surface for reflectance IR, the higher the signal-to-noise ratio could be. Hence the electrode surface must be polished very carefully.

Additional problems may be caused by the thin-layer geometry for EC-IRAS measurement, in particular time-resolved measurement. Mass transport in and out of the thin layer is strongly restricted, resulting in the change in the interface including the local pH and concentrations. In addition, the time constant of the spectroelectrochemical cell is very large due to the high resistance. Reactions cannot quickly respond to the externally applied potential changes. Furthermore, reactions occur first at the edge of the electrode and then gradually reach the center of the electrode. Therefore, time-resolved IR monitoring often becomes meaningless except for very slow reactions. To unravel this problem, the Kretschmann ATR configuration could be used, so that the IR radiation is passing through the ATR prism to irradiate on the backside of the ultrathin metal film surface evaporated on the prism. Since the evanescent wave that penetrates into the solution phase is damped by the metal films, the solution background is reduced significantly, so the solution phase does not need to be thin.\(^{(13)}\)
Alternatively, if the system studied is not restricted to single crystalline surfaces, one may consider changing the optical geometry from specular reflectance mode to diffuse reflectance so as to use rough surfaces. The increase of the surface area will inevitably increase the concentration of the surface adsorbed species. For certain kinds of surface, such as some noble and transition metal surfaces, this increasing of the surface area sometimes means the emergence of surface enhancement (SERS or SEIRAS). It is a quite common strategy that in the study of catalysis and solid–liquid interfaces, people find ways to increase the surface area in order to improve the surface sensitivity.

### 3.4.2 Surface Heating and Damage

Laser-induced sample damage is probably the second largest cause of unsuccessful sample analysis in surface Raman spectroscopy, especially for Raman microscopy. For a conventional Raman spectroscopic measurement, a 100 mW laser beam with a cross-sectional area of 0.785 mm² (diameter 1 mm) has power per unit area of 127 mW mm⁻². For a Raman microscope, the objective characteristic yields a 1-μm diameter beam waist at the sample focus. The power density at the focus is then in the order of 127 × 10⁶ mW mm⁻². This power confinement represents a million-fold increase in the power per unit area. The extent of these problems can range from subtle color or crystalline changes in the materials, to the complete ablation of the sample beneath the microscope objective. The heating problem is the main reason that high time-resolved Raman spectroscopy with a timescale of femtoseconds has not been applied to surface analysis because the extremely high power density could easily burn the sample surface. Even for the conventional Raman measurement, the heating may cause corresponding spectral changes, including subtle shifts in Raman transitions, the appearance of new transitions, or complete loss of signals. In order to prevent these possibilities from occurring, the following plan of action is suggested.

Prior to collection of a spectrum, a photograph or mental note of the sample’s appearance should be made. This photograph or note can then be compared to the appearance of the sample after a spectrum has been collected. If any changes have occurred, the sample will appear different. More subtle heating effects are best detected by collecting several spectra at different scan rates and/or power levels. If these spectra are not reproducible, the sample may be changing as a result of irradiation. If care is not taken during the analysis, the results can be easily misinterpreted. On some Raman microprobe systems it is possible to view the sample while it is being illuminated with the laser.

For these systems one can view the laser focus and determine whether it changes as a function of time. Should material be ablated from the sample, the size of the focused laser will appear large, since the remaining sample surface is below the microscope’s focus. Due to the fact that the objective is directly above the sample and in close proximity to the sample, any sample that is vaporized will condense on the cell window or the microscope objective. This material must be removed, since it will affect the focal characteristics of the laser and could yield a parasitic background in the Raman spectrum.

In the event that the sample undergoes degradation even at the lowest power levels, one of the more obvious solutions is to reduce the laser power still further. This solution can be implemented by defocusing the laser beam. Defocusing the laser is usually accomplished by adjusting the beam expander in the prefiltering optics of the system so that the objective’s aperture is under filled, so a large beam waist is obtained at the objective’s focus. If lowering the power of the laser decreases the sensitivity too much, an alternative way is to make a cell that can be moved horizontally or vertically using mechanical or pneumatic apparatus to minimize the thermal effects and damage very efficiently.

### 3.4.3 Fluorescence Elimination

One of the major problems associated with surface Raman spectroscopy is the elimination of parasitic fluorescence. Raman is a scatter-based phenomenon, inherently a two-photon effect. Fluorescence, on the other hand, consists of two sequential photon-induced transitions, and absorption followed by spontaneous emission. The timescale of scattering is on the order of 10⁻¹⁴ s, while fluorescence lifetimes are typically on the order of 10⁻⁸ s. Thus, the problem can be tackled using temporal fluorescence rejection techniques with a fast response rate detector. Fluorescence quenching is also a technique in which the sample is irradiated for a long period of time. After that, the fluorescence signal has been eliminated or reduced to a tolerable level. The use of an aperture at a remote image plane (confocal microspectroscopy) has also been employed in the elimination of fluorescence from near-neighbor locations. Although Fourier transform Raman spectroscopy has relatively low sensitivity, it allows Raman spectra to be recorded of many samples that fluoresce. This is because the samples are excited using near-IR excitation which does not induce sample fluorescence. Moreover, UV-Raman spectroscopy has been used in some situations very efficiently. An excellent example will be given in more detail in section 4.
3.4.4 Problems of Analyzing Spectral Data

In any process of interaction of electromagnetic radiation with matter, it is important to realize not only the advantages of each situation but also the limitations. There are potential traps where band distortions or intensity changes might have been interpreted as chemical or physical changes within the studied systems. In reality, they might have been simply artifacts attributed to various reflection or scattering processes. For instance, the IR radiation beam makes a double-pass through the film, having been reflected by the substrate. It must be remembered that superimposed on the essentially double-pathlength transmission spectrum will be a weaker specular reflectance spectrum which will mostly distort the stronger absorption bands, and in some circumstances cause band inversion. For thinner films the more specialized technique of grazing-incidence RA is instigated.

One often forgotten problem with ATR surface depth profiling is the fact that the relationships for depth profiling are valid only for homogeneous surfaces, that is, when the concentration of the surface species does not change. To overcome this problem, reflection theory for stepwise-stratified surfaces was successfully used to determine concentration changes at various depths. However, a fundamental difference between ATR and transmission spectra is the position of the bands and their intensities. The frequency shifts along with the sensitivity difference between high- and low-wavenumber regions, and spectral distortions near critical angle conditions, are the primary concerns in ATR quantitative analysis.

4 APPLICATIONS

IR spectroscopy and Raman spectroscopy are among the most widely used methods for surface science. Their ability to deliver specific chemical identification, coupled with the wide range of instrumental and sampling methodologies available, has led to their continuing use in both new and old venues in surface science. They are of prime importance in both fundamental research and various industrial fields related to surface oxidation, adhesion, corrosion and catalytic processes, and even open up the possibility of single molecular analysis. Their applications are reviewed well but briefly in the special issue of Analytical Chemistry published every two years. It is beyond the scope of this article to cover all applied fields. Only some typical applications in advanced materials, surface processing, catalysis, electrochemistry, corrosion, biology and sensor, which are related to future applicable areas, are given.

4.1 Advanced Materials and Surface Processing

4.1.1 Semiconductor Surface Processing

With the rapid development of materials science, IR and Raman spectroscopy has been used extensively to characterize various material surfaces as well as chemical processes occurring there. For semiconductors, surface structure change, electronic state mixing, nanoscale behavior (quantum well) and photoluminescence related materials have become routine measurements. More importantly, both techniques can be applied to in situ study of the chemical etching process of various semiconductor surfaces, in particular silicon surfaces, in varying etching solutions to determine the surface bonding and structure during or after the etching treatment or post-treatment of etched surfaces. The multiple internal IR reflectance with its high surface sensitivity and spectral resolution is sensitive to the atomic bonding configuration of the hydrogen in the vicinity of the surface, and permits an easy identification of bonding configurations of hydrogen on silicon surfaces. While the backscattering Raman measurement can be performed in a relatively convenient way, it enables the scrutinization of the etching mechanism of silicon surfaces. To increase the sensitivity, SERS studies of semiconductor ultrathin films (several nanometers) coated on SERS-active gold substrate have been reported, allowing investigation into the relationship between structure and physical properties.

4.1.2 Polymer Interfaces

Polymer–metal composites, which include engineering materials, adhesives and coatings, are of great interest in both science and technology. The study of functional polymers and other advanced materials provides numerous opportunities for the application of IR and Raman spectroscopy. Many reviews on this area have been given elsewhere. The rapid-scanning FTIR technique enables in situ time-resolved analyses, hyphenated studies of IR and mass spectroscopy, and on-line measurements to be carried out. It allows for the determination of crystallinity, composition, conformation, degradation and molecular interactions of polymers at surfaces and monitoring electropolymerization processes. For gaining high Raman sensitivity, SERS studies have been applied to determine the molecular structure of polymer–metal, polymer–solution and polymer–air interfaces. The polymers include polyaniline, polypyrrole, polythiophene, poly(vinyl pyridine) and poly(D-histidine), etc. The approach is achieved by covering the SERS-active surface with the thin polymer film or depositing SERS-active particles (islands) over the polymers chemically or electrochemically.
A good complementary SERS and IR study has been performed on a polythiophene film deposited electrochemically onto stainless steel.\textsuperscript{(47)} It displays a very interesting anisotropy property in electric conductivity, and the film parallel to the film surface is more than 10$^4$ times that across the film thickness. On the basis of the surface selection rules for SERS, the appearance of two new SERS bands is assigned to the molecular arrangement for the thiophene ring parallel to the metal surface for polymerization. According to the IR surface selection rule, the suppression of these modes parallel to the ring in the IR RA spectra strongly supports the same conclusion. The results suggest that the metal surface was coated with a layer of polymer in which the thiophene rings of polymer chains are nearly parallel to the surface.\textsuperscript{(47)}

4.1.3 Self-assembled Monolayers and Langmuir–Blodgett Films\textsuperscript{25,26,48}

There are numerous technological applications of thin films, such as electroluminescent devices, molecular devices and molecular sensing elements. Surface IR and Raman spectroscopy is one of the most widely used tools to characterize various organized monolayers and multilayers such as SAMs and LB films bound to or deposited on smooth surfaces. Because vibrational information can be obtained from all locations within the molecule of SAMs and LB films, for example, of self-assembled alkanethiol monolayers, the ordering and defect structure of the alkane chains can be directly investigated by observing G conformations of the carbon backbone.\textsuperscript{(48)} It has been shown that the alkane chain of adsorbed butanethiol is mostly in the all-T conformation, and the alkane chain of the adsorbed octadecanethiol appears totally free of G conformers.\textsuperscript{(48)} In contrast, adsorbed dodecanethiol shows a large number of G defects in the alkane chain. Based on the surface selection rule, these alkanethiols are proposed to be oriented with their alkane chain largely perpendicular to the surface with the S head group bonded to the surface. A chain tilt of ca. 15° with a rotation of ca. 45° about the chain axis is consistent with the surface Raman spectral intensities.\textsuperscript{(48)} The spectra quality obtained by confocal Raman microscopy is excellent. This will extend the study of ultrathin films, even monolayers, without the aid of SERS. Nevertheless, because of the relatively high sensitivity, IR spectroscopy has been used more extensively in this area.\textsuperscript{(25,26)} It is very useful for the study of the air–water interface of monolayer films, including fatty acids, fatty alcohols, fatty esters, octadecan and fluorinated undecanol. Raman spectroscopy can investigate the monolayers at the air–water interface with the aid of the SERS active colloidal Ag electrochemically grown underneath lipid monolayers. As the imaging measurement is very time-consuming, SERS imaging with a much faster acquisition time can be easily performed on a UV-photopatterned $p$-nitrophenol SAM and a SAM patterned by microcontact printing.

4.1.4 Zeolites and Molecular Sieves\textsuperscript{49,50}

As an advanced material, molecular sieves with atoms substituted by transition metal atoms in their framework have been considered as a new class of catalysts showing remarkable activity and selectivity for a number of oxidation reactions. The catalytic property is mainly attributed to the isolated transition metal atoms in the framework of the molecular sieves. Therefore, characterization of the transition metal atoms incorporated in the framework is the most important aspect of the study. However, it is extremely difficult to know how and whether the transition metal atoms are incorporated into the framework of a molecular sieve as special surface active sites inside zeolites. A new approach, UV resonance Raman spectroscopy, is used to identify the transition metal atoms in the framework of molecular sieves. This successful work is based on the resonance Raman effect since there are charge-transfer transitions between the framework oxygen and transition metal atoms in the UV region, see Figure 13. The characteristic Raman bands solely associated with the framework transition metal atoms are selectively enhanced so that the transition metal atoms in the framework of a molecular sieve can be definitely determined. For example, Ti atoms in titanium-substituted silicalite-1 (TS-1) were successfully identified using UV resonance Raman spectroscopy excited with

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure13.png}
\end{figure}
a 244 nm laser. The vibrational information of Ti–O–Si bonding is not detectable with a normal Raman system excited by 355 and 488 nm laser excitation (Figure 13). This demonstrated that titanium actually exists in the framework and gives powerful evidence for the predicted structure. Therefore UV resonance Raman spectroscopy has opened up the possibility of identifying the framework transition metal atoms in molecular sieves.449

Another important approach, picosecond IR spectroscopy, is used to study the dynamics of zeolitic protons and adsorbates. In the experiment, one specific vibration in the zeolite system is selectively excited with an ultrashort (tunable mid-IR) pulse. The effect of this excitation and the subsequent energy relaxation is monitored in real time, providing information on the structure of the bare zeolite and adsorption complexes. With this technique the picosecond energy flow at the catalytic site and the dynamics of the catalyst–adsorbate interaction can be investigated. Short-lived transient species are observed and the picosecond relaxation rates and pathways at the catalytic site reveal insights into the dynamics of the interaction between the zeolite and its adsorbate at a molecular level. This illustrates the potential of time-resolved IR spectroscopy in the investigation of zeolite systems.50

4.2 Catalysis

4.2.1 Adsorption and Reaction on Catalysts

In situ application of IR and Raman spectroscopies to catalytic study benefits from the state-of-the-art design of the in situ cell (or reactor) and the continuous development of instruments and light sources operating from near-IR to the UV region. It offers a number of potential advantages over other vibrational spectroscopy techniques in the characterization of real catalysts since it could obtain information about both surface adsorbed species and the structure of catalysts under working conditions. In particular, Raman spectroscopy has been applied extensively in determining the low frequency vibrations of oxide and oxide-supported catalysts. Furthermore, it is useful in identifying phases that are present in precursor stages of the catalyst during its preparation. Recently these two techniques have been used to characterize the surface species present and its reactivity with other gas or adspecies on catalysts at high temperatures.51 For instance, syngas reaction reforming of methane on catalysts has been the subject of extensive investigations. Raman scattering has been particularly invaluable in three aspects: determination of catalyst oxidation state, evaluation of the role of the support, and identification of adsorbed intermediates. The time-resolved technique is widely employed to determine catalytic reaction kinetics, and identification of the reaction intermediates.52 The adsorption of oxygen on the catalyst surface and the interactions of oxygen species (O2^2-, O2^- and O2^δ^- (0 < δ < 1)) with methane, ethane and ethene from room temperature to high temperatures (up to 1073 K) were studied with the aid of a high sensitivity confocal microprobe Raman system. The high signal-to-noise ratio provided enables the time-dependent study of the oxidation process, thus the adsorbed species and the change in the structure of catalyst can be investigated.53

4.2.2 Probe Molecules for Catalytic Study

In addition to identifying adsorbed species, IR spectroscopy and Raman spectroscopy are also used to monitor and analyze surface adsorption sites and reaction sites indirectly by observing the spectral change of an adsorbate known as the probe molecule.54 In practice, CO is most frequently employed for this purpose, although NO and N2 have also proved suitable on occasions. Wavenumber and band shape of the νCO are very sensitive to the chemical and electrostatic environment as well as to the mode of surface bonding that is dependent on the nature of adsorption site, coadsorbed species and surface coverage. This characterization of surface structure constitutes a major in situ application of IR, since it can be used to monitor changes in the catalyst during reaction. Moreover, examining the overall effects of electrode potential, together with the more specific influences of the solvent medium, electrolyte ions, and other adsorbates upon the vibrational spectrum of adsorbed CO provides a means of elucidating structure and bonding in metal–solution systems. To examine some more complex surface systems, two different probe molecules such as CO and NO conjunctly adsorbed on the surface with different concentration together with the isotropic experiments are used for gaining detailed structural information of surface active sites.

4.3 Electrochemistry and Corrosion

4.3.1 Electrocatalysis

Electrochemistry is one of the most “hot” areas because the vibrational data provide insight not only into the structure and orientation of adsorbates, but also regarding the nature of local interactions with the surrounding solvent, ions, and the surface, as well as with the variable electrostatic fields. Electrocatalysis is the central topic in the study due to its importance both fundamentally and industrially, which is related to fuel cells, batteries and electrochemical synthesis. IR spectroscopy has been shown to be very useful for the characterization of catalysts, determination of
catalytic reaction kinetics, and identification of the reaction intermediates. The richest information has been gained from the electrochemical behavior of small organic molecules (e.g. alcohol, formaldehyde, formic acid) on adsorption, dissociation and oxidation on transition metal surfaces (Pt, Pd, Ru, etc.).\(^{55,56}\) Although EC-IRAS can be applied to any material surfaces, its drawback is that only smooth or mild rough surfaces with reasonably good reflectivity can be used when using the RA mode, which is the most commonly used method.

Recently, SERS study has been successfully extended to many bare transition metals of practical importance, in particular for electrocatalysis.\(^{57}\) The remarkable advantages should be pointed out. The sample studied can be very dark in color and with highly rough surfaces. This means that practical catalysts can be directly investigated in situ. Moreover, the metal–adsorbate vibrational modes located in the low-wavenumber region can be easily observed, providing significant information about surface bonding of the adsorbate surface. The complementary study of IR and Raman will ensure a better level of understanding of adsorbate structure and surface bonding, and eventually of electrocatalytic reactivity.\(^{28}\)

4.3.2 Electrochemical Double Layer\(^{13,28,57}\)

Understanding the composition and structure of the electric double layer formed at the electrochemical interface constitutes one of the major objectives in electrochemistry. In particular, detailed knowledge of water molecules at the interface is an essential prerequisite to understanding electrocatalytic reactions. Unfortunately, the signal from interfacial water is overwhelmed by that from bulk water. SEIRAS with ATR configuration can probe the interface without the interference from the bulk solution and, hence, has been used to investigate the potential-dependent reorientation of water molecules at the Au(111) surface. Figure 14(a) shows a series of IR spectra from the electrode surface in perchloric acid, collected during a potential sweep from 0.1 to 1.3 V. The intensities and shapes of the \(v\)OH and \(\delta\)HOH modes of water change significantly as the potential changes, indicating different orientation of water molecules at the interface, see Figure 14(b). In the potential region around 0.6 V, the flat-lying water molecules do not give IR absorption because of the surface selection rule. Furthermore, the dynamics of the water reorientation caused by a potential step was studied at a time resolution of 10 \(\mu\)s. The spectra showed that the reorientation of water occurs within the initial 1 ms and is followed by the adsorption of electrolyte anion. Very recently, successful extension of SERS to the study of transition metals invoked substantial interest in electrochemical adsorption of hydrogen, oxygen, (pseudo-) halide ions and their coadsorption on transition metals.\(^{58}\)

4.3.3 Corrosion Processes\(^{22,59}\)

Early Raman study of the corrosion process involved the borrowing of the SERS effect of silver overlayers or sub-layers to investigate the passivation film and the adsorbed corrosion inhibitors. The results become complicated with the introduction of Ag. The sensitivity provided by Raman and IR microscopy makes in situ investigation of the corrosion process under working conditions
